SURGERY AS A SCIENCE AND ART IN THE CITY OF NEW YORK IN THE MIDDLE OF THE LAST CENTURY.*

By STEPHEN SMITH, M.D., LL.D.

NEW YORK.

Surgery as a science and an art in New York in the middle of the last century can be most thoroughly understood and critically estimated by a knowledge of the surgeons of that period, the methods and success of hospital practice, the character of the instruction imparted in the medical schools, and the contributions to current surgical literature.

The representative surgeons of New York in 1850, or those who were most prominent as teachers, hospital surgeons, and authors, were nine in number and may be properly classified according to their respective ages, as follows:

Over 50, Valentine Mott, 65; John Kearney Rogers, 57; Willard Parker, 50.

Over 40, Alfred Charles Post, 45; John Watson, 43; Gurdon Buck, 43.

Over 30, James Rushmore Wood, 34; John Murray Carnochan, 33; William Holme Van Buren, 31.

Of these three groups of surgeons whose names are now historical in the annals of American surgery, the first represented in teaching and practice the new era in the science and art of surgery created by the school of Hunter. The preceptors of some of these surgeons had been pupils of that great pioneer in rational surgery and had imparted to their students the scientific spirit with which they had been inspired by the master.

Conspicuous in this class was Mott, the senior surgeon of the three groups, whose brilliant career was now drawing to its close. By natural endowments, preparatory training, and fitting opportunity, he was eminently adapted for the work which he so successfully accomplished. In reviewing his life-work it is apparent that the conditions which conspired to win success were, *Aptitude—Training—Opportunity.*

Physically, Mott was of large stature. Throughout his professional career his imposing personality, dignified by a conscious sense of its superiority, attracted the attention of even the passer-by. Mentally, his special endowment was the gift or faculty for the most painstaking attention to details. This was noticeable in his study of any subject before he would reach a conclusion; in his careful preparation for the simplest operation, and especially in the actual manual procedure when his conclusion was put to a practical test.

*Address delivered at the semi-centennial anniversary of the New York Academy of Medicine.

Mott's training for his future work was of the highest order. The son of a physician resident on Long Island, he early became a pupil of Dr. Valentine Seaman, a relative, then a prominent surgeon of New York. Later he came under the instruction of Dr. Wright Post, professor of surgery in the medical school of Columbia College. No person could have been selected better adapted to develop into full and vigorous activity the native attributes of the mind of his pupil for his future achievements than Post. Mott thus speaks of his preceptor:

"He was unrivaled as an anatomist, a most beautiful dissector, and one of the most luminous and perspicuous teachers I have ever listened to, either at home or abroad. His manners were grave and dignified; he seldom smiled, and never trifled with the serious and responsible duties in which he was engaged, and which no man ever more solemnly respected. . . . As an operator he was careful, slow, and elegant, and competent to any emergency contemplated by the then existing state of surgical science."

To these important qualifications as a teacher Post added that of an ardent student of the school of Hunter. He was probably present when Hunter performed the crucial operation of ligation of the femoral artery for popliteal aneurysm, in 1785, by placing the ligature at a distance from the tumor on its proximal side. The explanation of that operation by the operator, its novelty, and its successful issue must have inspired Post with that zeal for operative surgery which characterized his subsequent career. While Mott was his pupil Post performed the Hunterian operation for aneurysm several times with success. On his graduation Mott visited London and for two years was the private pupil and assistant of Sir Astley Cooper, then the foremost operating surgeon of Europe. During that period he assisted Sir Astley in a large number of the most difficult operations, of some of which he has given graphic accounts showing his intense interest in operative surgery. While in London he attended the clinics of the two Clines, Abernethy, the two Blizards, and Sir Everard Home, the brother-in-law of Hunter. Subsequently he attended lectures at the Edinburgh School, made famous by the Munroes.

On his return to New York in 1809 Mott was fully equipped for the great opportunities which awaited him. Nor did he fail to improve them. The field of operative surgery was occupied by Post, his preceptor and friend, who was about to retire from the more active duties in school and hospital. By patient and persistent effort Mott succeeded to the positions thus made vacant, first as a teacher of surgery, and second, as an operator and in both he more than maintained the reputation of his predecessor.

A critical study of Mott's practical methods re-

veals the special feature on which his remarkable success depended. His operative wounds rarely suppurated. Healing by first intention was the rule. This was a result sought for by Hunter, but at that period never so completely obtained by operators as by Mott. We now discover that his very habits of personal cleanliness and attention to every detail however minute secured in a large measure asepsis of the operated wounds. His personal neatness and precision in dress attracted the notice of the public to the extent that persons often gathered in front of his house to see him enter his carriage, which was always at the moment fixed for his morning visits. It was stated by a domestic that the floor of his dressing room would be found strewn with linen on which he had discovered a "fly-speck." The late Prof. Joseph M. Smith, who was a medical student when Mott began his first course of lectures, said, "When Dr. Mott appeared in the lecture room of the College of Physicians and Surgeons, soon after his return from Europe, in company with the professor, his appearance made a marked and most favorable impression on the class. His dress was scrupulously neat, his hair powdered, and his bearing courtly and dignified. All of us regarded him with a feeling of deference amounting to awe."

His attention to details was of the most exhaustive kind. Order prevailed wherever he had control in office, clinic, and hospital. He prepared for operations even of an unimportant kind by dissections and a review of its simplest feature. He invariably cleaned his instruments immediately before as well as after an operation. As an illustration of his personal cleanliness one of his students states that on going to the office one morning he found the doctor examining an abscess. He requested the student to open the abscess, which he proceeded to do, and meantime the doctor, rolling up his sleeves, placed his hands behind him and, stooping over the part, watched the process. When the pus began to flow he expressed his satisfaction with the operation and went to the bowl and washed his hands.

The crowning event in Mott's many great achievements was placing a ligature around the innominate artery. It was the most brilliant operation ever undertaken by any surgeon to that date. Nor has it been excelled in genius of conception and skill of execution if we give due consideration to the conditions under which it was performed. It was the ripe fruit of years of study and preparation. He says: "Since the publication of Allan Burns's invaluable work on the 'Surgical Anatomy of the Head and Neck,' I have been in the habit of showing, in my surgical lectures, the practicability of securing in a ligature, the arteria innominata, and I had no hesitation in remarking that it was my opinion that this artery might be taken up for some condition of aneurysms, and that a surgeon with a steady hand and a correct knowledge of the parts would be justified in doing it." Mott always spoke of his excision of the clavicle as his "Waterloo operation," partly because it was performed on the day preceding that battle and partly because he thought it his greatest operation.

In 1851 Mott appeared in a new position. Owing to changes in the faculty of the University Medical College which he did not approve he resigned his professorship in that school and was elected professor of "operative surgery" in the College of Physicians and Surgeons, in which he began teaching surgery forty years before. He delivered his introductory lecture to the course November 7, 1851, before a large audience of medical men, his subject being "Reminiscences of Medical Teaching and Teachers of New York."

Mott was now at the zenith of his greatness, not only as regards his fame as a surgeon, but as to his imposing personality. He had just returned from a tour of the European capitals, where he was universally received with the most distinguished honors. On the occasion of the delivery of his lecture his dress was faultless, his manners courtly, and his bearing that of one who is conscious of his superior rank. While he alluded to his contemporaries in terms of measured respect and deference, and reviewed the work of the surgeons of the past half century in terms of praise, he adroitly quoted the famous passage of Virgil,

Et quorum pars magna fui,

which brought a smile to the faces of the older surgeons on the platform.

A familiar acquaintance with Mott in the later years of his life revealed traits of character altogether admirable. The breadth of his studies embraced a large range of the physical sciences; he was a devoted lover of truth as it was developed in every department of research; his humanity was shown in his address on the condition of the tenement population of the city; his ideas of right citizenship appeared in his efforts to secure our present Health Department; his patriotism was conspicuous during the Civil War. Underlying these mental and moral endowments, as an abiding foundation, was a profound religious faith. Heroic men often epitomize the distinctive features of their lives in their dying words. Napoleon's last words were, "Tête d'armée." Mott's last words were, "Order, truth, punctuality."

Rogers, a native of New York, was also a student of Wright Post and a surgeon to the New York Hospital. He was tall and lean with strong features and spoke with apparent diffidence. He was seen and heard only at occasional clinics and operations at the New York Hospital. In operating he was very precise and rapid, two features of an operation regarded in the preanesthetic period, in which he performed his most notable operations, of the first importance. Rogers' reputation rested upon the single operation of placing a ligature around the left subclavian artery, within the scalenı muscles. This operation was scarcely second to that of ligation of the innominate, especially in the dissection necessary to expose the artery. It is an interesting fact that Mott, who was one of the consultants, opposed the operation, though he admitted that it might possibly "be tied by a careful and well informed surgeon," but he "considered it improper to do so." Sir Astley Cooper had failed in an attempt to ligate this artery, and that circumstance doubtless stimulated Rogers to make thorough preparation for the great undertaking. He said, "I had always considered it as a perfectly justifiable operation, and one that a careful surgeon conversant with anatomy could accomplish if the tumor were of moderate size."

The final consultation of the surgeons resulted in committing the question of operation entirely to the discretion of Rogers. He accepted the responsibility and proceeded with the operation. It proved to be as formidable as was anticipated, but he succeeded, and for several days there was a fair promise of recovery of the patient, but a fatal hemorrhage occurred on the thirteenth day. Rogers'

comment on the operation was: "From the knowledge thence derived we shall be able to enlarge our sphere of usefulness and be the means of preserving human life."

Parker was professor of surgery in the College of Physicians and Surgeons, a position which he had held for ten years. He was a native of New Hampshire, a graduate of Harvard College, and a pupil of Dr. John C. Warren of Boston. In 1850, and at the age of 50, Parker was a splendid specimen of mature manhood; his large, muscular frame was crowned with a well-poised head; his features indicated energy, earnestness and activity; his speech had the tone of command and authority. He was not a student, nor an investigator, but an intensely practical surgeon. His mental attributes and temperament rendered his teaching practical rather than theoretical. This peculiarity of his teaching, with a plain but forcible style of address, was very attractive to students, and especially to practitioners. His contribution to practical surgery which has attracted most attention was an operation in suppurative appendicitis, which has been regarded as the origin of the method of treating appendicitis by excision in the early stages of that disease. Although Parker's operation may have been a step in that direction, it was not his purpose to operate before pus had formed and could be detected. At the time of that operation two opinions were held in regard to the time when an abscess should be opened, viz., whether it should be opened as soon as pus is detected, or after the abscess had "ripened"—"come to a head." Parker taught that it should be opened when pus is detected and accordingly he opened an abscess caused by appendicitis at this early stage and the patient made a good recovery. Hancock of London had previously operated in a similar manner and with success. These operations for abscess of appendicitis led to the exploration of the wound and removal of the diseased appendix, and finally to the operation for the removal of the appendix before an abscess formed, or as soon as appendicitis is diagnosticated.

The second group of surgeons—Post, Buck, Watson—were all surgeons of the New York Hospital, the scene of Mott's and Rogers' great achievements. No one in this group made any pretensions to a reputation in the field of operative surgery. They held clinics during their terms of service, but these were conducted in a manner to attract but few students. Post's clinics were of interest chiefly owing to his accuracy of statement in explaining the disease of the patient, but his personal manners and style of speaking were entirely without the vigor and enthusiasm with which Parker inspired students in his college clinics. Buck was a laborious and painstaking surgeon whose clinics were entirely wanting in everything like glamor, and students were attracted to them by the instructive methods which characterized his treatment of every case and the patient attention which he gave to every detail. He described the case in a few words, spoken in a low tone, and performed operations in the most leisurely manner. Throughout the clinic he impressed the student with his conscientious devotion to the welfare of the patients quite regardless of the impression which he might make on his audience. On one occasion it was advertised that he would remove a urinary calculus by crushing the stone, a novel operation at that time which attracted the leading surgeons, and a crowd of students. Buck explained the operation in a few words, exhibited the instruments with which it was to be performed, stated that the stone had been readily detected with an instrument the day previous, and proceeded with the operation. After a brief search he withdrew the instrument, remarking with evident embarrassment that he had failed to discover the stone, and that it was necessary to allow the bladder to rest before making farther search. His second effort proved a failure, as did a third, whereupon he announced to the intensely disappointed audience that the patient's bladder had been irritated as much as was safe and he would adjourn farther proceedings to his next clinic. There were mutterings of disgust at his want of tact and skill, but Mott and Parker complimented him on his conservatism.

Buck was evidently much embarrassed in his operations by an extreme myopia, but though there was no brilliancy in his methods he had the reputation of being one of the most successful surgeons in the city as regards the recovery of his patients. This success was due to his extreme care of the patient before and after an operation. It was said by a house surgeon of the hospital that he was often aroused at a late hour of the night by a visit of Buck to patients on whom he had operated during the day, an incident quite unusual in the practice of other surgeons.

Watson was generally regarded as a very scholarly surgeon, and the courses of lectures which he occasionally gave in the hospital attracted a select class of students. But as a practical teacher in clinics, and as an operator he failed to interest either the students or the profession. His reputation as a scholar rests on an address before the Academy of Medicine on the "Medical Profession in Ancient Times," delivered in 1856. Watson was a native of Ireland but came to this country at the age of three years and was a graduate of the College of Physicians and Surgeons.

The third group of surgeons—Wood, Carnochan, Van Buren—was a reversion to the first type, in this, that each one was an operator and a teacher. They were not connected with the New York Hospital, but represented an ambitious class of thoroughly equipped young surgeons who were compelled to seek hospital privileges and opportunities elsewhere than in this quite exclusive institution. Wood and Van Buren became surgeons to the recently created Bellevue Hospital and Carnochan was made surgeon-in-chief to the Emigrant Hospital on Ward's Island.

Wood's great service to the profession of the city and to the cause of medical education in this country was the conversion of Bellevue from a disreputable almshouse to a well-organized modern hospital, and, finally, in inaugurating in its wards clinical instruction as a necessary part of a medical education. This change he effected—1844-1861—after a prolonged and intense struggle with the civil authorities. The opening of a new hospital was a great benefit to aspiring young surgeons, for the opportunities to enter the New York Hospital were so few and far between that appointments to its surgical staff were remarkable events.

The new Bellevue Hospital became, and remained during his lifetime, the theater of Wood's achievements in surgery. His clinics, the details of which were carefully prepared, were very attractive to the students in the medical schools on account of the variety of operations performed, the brilliant display

of instruments, and the frequent dramatic incidents which occurred during the operation. Wood was a good speaker, and while his lectures lacked breadth and scope, and his diminutive stature detracted from his personality, the intensity of his convictions and the energy with which he enforced his opinions never failed to interest the student. But it was in the manual part of the operation that he was at his best.

Carnochan, a native of Savannah, Georgia, was of Scotch descent by his father, but his mother was a grand-niece of Gen. Israel Putnam, of Revolutionary fame. He received his academic education in the schools of Edinburgh and London. He was a brilliant scholar and took the first rank in high-grade schools. While resident in Edinburgh he was brought into close relations with Professor Wilson, in philosophy, Hope in chemistry, and Knox in anatomy, and these associations are believed to have influenced him in the choice of his profession. On returning to this country he became a pupil of Dr. Valentine Mott, and was graduated from the College of Physicians and Surgeons. He then went abroad and studied at the École de Médecine, Paris, and for six years devoted himself to the practice of the hospitals in that city, becoming thereby intimately acquainted with the leading surgeons of the French capital. He then visited London and attended the lectures and hospital practice of Cooper, Brodie, Liston and others. In 1847 he began practice in New York and was appointed surgeon-in-chief to the Emigrant Hospital on Ward's Island in 1850, and in 1851 he was elected to the Professorship of Surgery in the New York Medical College.

Carnochan was by nature and education thoroughly equipped for a successful career, both as a teacher of the science and a practiser of the art of surgery. He was of large stature, courtly manners, deliberate and precise in speech, and very dextrous in operations. He did not, however, secure the position in the profession of the city to which his abilities and achievements entitled him owing to his failure to be in accord with the prevailing ethical sentiments that at this period governed membership of medical societies.

Van Buren, the junior surgeon of the three groups, was regarded as giving promise of a career in surgical teaching and practice only second to that of his father-in-law, Valentine Mott. He descended from a long line of eminent physicians, was educated at Yale College, and took his degree in medicine from the Medical Department of the University of Pennsylvania, had studied in the hospitals of Europe, had been a surgeon in the army, and was associated with Mott in practice. No surgeon in the entire list combined so many personal and acquired qualities making for success, whether as a teacher, author, or practiser. In personal appearance he was faultless, being above the medium height, his features classical, his manners affable, his style of speech deliberate and precise, but never self-assertive, and his method of operating very exact in every detail without the slightest effort to create a sensation. These qualities united to make him a favorite of students, and his clinics at Bellevue, to which he was a surgeon from its reorganization, were always well attended.

From this sketch of the *personnel* of the surgeons who, in 1850 were the acknowledged representatives of surgery as a science and an art in New York, we pass to consider the quality and character of the didactic teaching in the medical schools.

The professors of surgery in the two schools were Prof. Willard Parker in the College of Physicians and Surgeons, and Prof. Samuel D. Gross in the University Medical College. As Dr. Gross came from Louisville, Kentucky, to give a single course of lectures, he did not represent the profession of New York in any respect. Parker's lectures were almost entirely devoted to practical subjects.

As a practical teacher Parker appeared to the best advantage in the college clinics. Here he explained, in a familiar, conversational manner, the diseases of the patients and the methods of treatment, as they were brought before the class. This clinic was very popular, as it illustrated the daily practice of the physician in the succession of cases which he was likely to meet, and the prompt method of diagnosis and treatment required. Parker was a very careful and deliberate, ambidextrous operator, without any effort to attract attention by an exhibition of dexterity.

It should be stated of Professor Gross that he had been invited to give the course of lectures on surgery in the University Medical College with a view to occupying the position permanently. He was a personal friend of Parker and was ambitious to settle in New York. Parker's experience on coming to New York from Cincinnati, ten years before, to accept the Professorship of Surgery in the College of Physicians and Surgeons, was attended with so many discouragements that he strongly advised him against his contemplated change. Gross declined the position, but afterwards accepted an invitation to the Chair of Surgery in Jefferson Medical College, Philadelphia, and made his future residence in that city.

Whatever defect there may have been in the systematic teaching of surgery in the colleges, there was no deficiency in the quality and quantity of clinical instruction in the hospitals. The New York and Bellevue Hospitals were rival centers of surgical instruction and practice in 1850. They were, however, very unlike in organization and management. The New York Hospital had been established three-quarters of a century and was modeled after the London hospitals of that period. Everything about it had the air of age and respectability. Its visiting staff was composed of the elder physicians and surgeons, some of whom visited the wards in evening dress. They as well as the chief officers performed their duties with a stately precision that impressed with awe the class of students. There was a solemnity about the public clinics which reached its climax when the visiting surgeons and invited guests came slowly in with measured tread. The lecture of the operator was given in a subdued tone and throughout the operation an oppressive silence prevailed.

The practice of surgery at the New York Hospital was along the conservative lines established by Wright Post, Mott, Stevens, and Rodgers. The most scrupulous attention was given to every detail of diagnosis, prognosis, and treatment. Formal consultations were held on all operative cases. In the wards interest centered in fractures, especially compound fractures of the leg and fractures of the thigh, and neck of the femur. The former was treated in boxes partly filled with bran, as an absorbent of the abundant flow of pus, which was regarded as a great improvement. The question in fractures of the femur was, the kind of splint and method of traction, and many varieties were submitted for criticism—a question finally settled by

Buck's employment of adhesive plaster, weight, and pulley. Whether a fracture of the neck of the femur was within or without the capsule afforded infinite speculation as it involved the question of union by bone. The use of anesthetics—whether ether or chloroform should be preferred—was a living question. Deaths had occurred from both, but more suddenly and mysteriously from chloroform, and the latter was rarely given, and the former was employed only in major operations. Of operations amputations attracted the largest attendance of students and was the chief major operation.

At Bellevue the conditions were entirely changed. The hospital was in the first stage of evolution from an almshouse, and many of the vices of its former management still prevailed. Most of its nurses and attendants, and many of its subordinate officers, had once been inmates as paupers, owing to their previous habits of intemperance. But its visiting medical staff was composed of ambitious young physicians and surgeons, of a high grade of qualification, who were animated by the common purpose of making Bellevue popular with students and the profession by a well-organized system of clinical instruction.

The surgical practice of Bellevue was largely confined to chronic diseases, an inheritance of the almshouse. Ulcers, caries of the bones and joints, syphilis in every form and stage, and pus-generating affections filled the wards. Pus abounded, and scarcely a clean, healthy wound was known. While a junior in the resident surgical staff it was my duty to carry the dressings from bed to bed, twice and three times daily, while the house surgeon, Dr. John Moore, afterwards Surgeon-General of the United States Army, removed with long forceps from the dripping wounds the offensive, saturated materials. Healing of wounds by "first intention" was unthought of, and was, indeed, unthinkable.

But this abundance of chronic, suppurating diseases, the accumulation of years, proved to be invaluable to the surgeons, for they furnished large opportunities for amputations and excisions of bones—the major operations of that time. Thus the surgical clinics at Bellevue early assumed a special interest to students. There was also in the atmosphere of the hospital that social familiarity between the visiting and resident staffs and the students which the latter so highly and justly appreciate. This freedom and familiarity was due in part to the former almshouse character of the hospital, but more largely to the fact that the medical officers were young men ambitious to excel as teachers, several of whom had been trained at the clinics in the hospitals of Paris. They appeared in the wards, not in evening dress, but in a ward garb, and greeted the students as fellow workmen. Every possible attention was given to the students who were freely admitted to the wards and were not only allowed, but frequently were required, to examine the patients, a great privilege at that time.

But the public clinic at which an operation was to be performed was most attractive to students and to the profession. These were often most spectacular affairs, and aroused the greatest enthusiasm in the audience. This was especially true of Wood's clinics. Amputation of limbs was Wood's star operation, and care was taken to make it impressive. On entering the operating room the student, dazzled by the array of instruments covering the tables, was impressed with the gravity of the operation. At the appointed moment the operator appeared, faultlessly dressed, a boutonnière in the lapel of his coat, and followed by a retinue of invited guests. The students applauded with genuine delight. The operation was described briefly, and the instruments to be used were displayed and fully explained. The operator donned his operating suit and the preliminaries were arranged. There was a momentary hush, as each assistant took his position, and the operator, grasping the limb, called for the first instrument. The nervous tension of the students increased as they witnessed the gleam of the catlin, the flinging away of useless instruments, the sharp commands of the operator, the rapid action of the saw, and, as the severed parts fell, there was a tremendous outburst of applause.

It is not surprising that Bellevue, though at that time very inaccessible, soon became the favorite resort of students. Under the leadership of Wood, and infinitely to his credit, the clinical instruction of the hospital increased in systematized form, until courses of clinically illustrated lectures assumed a post-graduate character. The necessary result was that within a decade a fully equipped medical college was established within the precincts of the hospital, which has borne an honorable record among similar institutions in this country.

The contributions of the surgeons of New York to surgical literature in 1850 were in the form of cases with critical remarks. That they did not produce elaborate treatises was not from any want of ability as writers, but because bookmaking was not as to-day the popular method.

Looking backward from the viewpoint of more than half a century, the surgeons of 1850 appear physically and mentally of heroic mould. Their achievements under conditions now regarded as absolutely preventing success were even more remarkable than the marvelous deeds of the surgeons of the twentieth century. It is true that objects appear larger in the dawn than at midday, but, making all due allowance, several of the surgeons mentioned in this review have no peers in these latter days. They were pioneers blazing the pathway of future progress in the dim twilight of the day now made luminous by the sun of science at the zenith.

SUPERFICIAL AND DEEP SENSORY DISTURBANCES IN THEIR RELATION TO ASTEREOGNOSIS AND ASYMBOLIA.*

By ALFRED GORDON, M.D.,

PHILADELPHIA, PA.

ASSOCIATE MEMBER OF THE SOCIÉTÉ MÉDICO-PSYCHOLOGIQUE IN PARIS, FRANCE; NEUROLOGIST TO MOUNT SINAI, NORTHWESTERN GENERAL AND DOUGLASS MEMORIAL HOSPITALS.

THE study of sensory disorders has been the subject of considerable literature. Sufficient material has already accumulated on the question of special sensations. A careful review of all published observations concerning the question of astereognosis leads to the deduction that it is highly important from a scientific and practical standpoint to make a discrimination between a loss of the faculty of recognizing the form and shape of an object and a loss of the faculty of recognizing the nature of an object. It has been the custom with many writers to confound these

*Read before the Philadelphia Neurological Society, March 25, 1910.

two different functions and to describe them under one name, (astereognosis). In face of all the cases observed and recorded such a tendency must be abandoned, as it is at variance with clinical facts. Cases with preservation of stereognostic perception and loss of symbolic perception and *vice versa* are well known. There are sufficient evidences showing that one may exist without the other and that they are therefore independent cerebral phenomena. Apart from general sensations which will be considered later, an idea of an object can be formed principally in two ways. One is what Wernicke calls primary or simple identification and consists of identification or recognition of the form of an object. This is the genuine stereognostic sense. But the knowledge of the form of an object does not constitute the knowledge of its nature. The latter is a complicated perception of a higher order and has been aptly called secondary identification, or for want of a better term, symbolia. (Claparède). Astereognosis, therefore, is an inability to recognize the form and asymbolia—an inability to understand the nature of an object and to name it. The contention has been that the recognition of form and nature of objects is dependent upon the integrity of all elementary sensibilities, such as touch, pain, temperature, pressure, movements, posture, etc., etc. *A priori* one must concede that a perception of a high intellectual order such as form and nature of an object is the result of association of all individual senses, also of impressions produced by visual images. But when we attempt to analyze carefully the cases that come under our observation, we find that this exclusive view does not altogether solve the problem, and that the subject under discussion is more difficult than one may presume. In the present essay facts will be brought forward showing that the generally accepted contention cannot be maintained. It corroborates the view of the few writers who believe in separate perceptions for form and nature of objects. Moreover, it shows that stereognostic sense may be totally preserved in spite of pronounced alterations in the deep sensibilities, which, according to many writers, are essential in preservation of that particular perception. The cases are as follows:

Case I.—M. M., aged forty-five, tailor by occupation, after a brief period of dizziness and nausea was suddenly stricken with an apoplectic seizure in March, 1909. He lost consciousness, and when he regained it at the end of fifteen minutes he was unable to speak and lost power in the right upper limb. The loss of speech lasted but forty-eight hours. During the following six weeks his arm kept on improving and finally recovered. Two months later he came under my observation and the following notes were taken: There was a slight asymmetry of the face. When he laughed the left nasolabial fold was more marked than the right. The power of the right arm and forearm was good. The grip of the right hand was weaker than that of the left. This hand showed some ataxia which could be demonstrated by asking the patient, while his eyes were closed, to put individual fingers on the nose, ear, chin, or buttons of the coat. There was some difficulty in abducting and adducting the fingers. The little finger was in constant abduction. When the right hand was stretched out and the fingers were extended, there was immediately an involuntary attempt to flex the fingers; extension could not be kept up for longer than a few seconds. When the fingers were extended, the middle finger was always above the level of all other fingers. There was a considerable amount of awkwardness in his right hand and particularly in the thumb and forefinger. While there was a great deal of power, he, nevertheless, could not get a good hold of objects. He had great difficulty in buttoning or unbuttoning, or tying and untying his necktie; he spent much time on his toilet; threading a needle was an impossibility; holding a penholder or pencil was difficult.

The skin of the right hand and fingers was cyanosed and smooth. There was some wasting in the muscles of the hand. The sensory disturbances which constituted the most conspicuous feature of the case will be discussed in detail later. Station and gait were good. The patellar reflexes were increased equally on both sides. No other abnormal tendon or cutaneous reflex was present. The patient's previous medical history was practically negative. Specific infection was denied. He drank whiskey for a number of years but only one or two wineglassfuls a day. He smoked excessively, about twenty-five cigarettes a day. He complained of continuous severe headache and vertigo. The heart sounds at the apex were normal but at the aortic orifice the second sound was much accentuated. The pulse was of high tension and the peripheral arteries were somewhat hard. The urinary examination was negative. The pupils reacted promptly to light, accommodation, and convergence. The fundi were normal. There was a slight obscuration of disc margins in both eyes (report by Dr. S. H. Brown).

Examination for sensations revealed the following interesting phenomena: The sense of touch, pain, and temperature was well preserved on the entire hand, dorsum, and palm, also on both surfaces of each individual finger. The tactile sense was investigated with VonFrey's method—a camel's hair and absorbent cotton were used. As a matter of detail it may be mentioned that when the middle finger was touched he pointed to the ring finger and *vice versa*. This occurred several times but not every time during the examination. Another abnormality was that when the palm was very gently touched with cotton, the touch was not always perceived. The remainder of the hand and fingers was normal to touch. Pain sense was tested with a pin and my precision esthesiometer (*Journal of the American Medical Association*, April 17, 1909), and was found to be normal. Some deviation from normal was revealed by an accurate test for temperature. Extreme heat and cold being used, there was a diminution of heat sense on the palmar surface of the thumb, forefinger, and middle finger, and the palm of the hand, but on other parts of the hand heat was correctly perceived. Cold was normally felt over the entire hand and fingers. Pressure sense was tested by placing different weights and by exerting direct pressure with the finger of the examiner. With the latter method great care was exercised to produce the same degree of compression. The test being applied to the palm, dorsum, and both surfaces of each individual finger; everywhere the sense was found to be normal. Localization sense of the right hand was determined by the naming, looking, and spacing tests. The naming test, which consists of having the patient tell the spot touched while his eyes are closed, was found in this case to be positive over the entire hand and fingers except over a small area in the

center of the palm where occasional mistakes would be made. The looking procedure (Volkmann's and Spearmann's) which consists of pointing out the touched spot by the patient after his eyes have been closed during the touching, and after the impress made on the skin has disappeared, presented here no alterations over the entire hand and each finger on all their aspects. The spacing test, which consists of touching with two points of the compass or with one point after another, presented in my case marked changes in the perception of the number of points. Thus on the palmar and dorsal surfaces of the thumb and forefinger two points separated from each other at a distance of a half of an inch were taken for one and on the palm the same was observed even at a distance of three inches between the points. When one point of a pin was applied immediately after another, no error was discovered in their recognition over the entire hand and fingers. An effort was also made to determine whether the points touched were nearer the shoulder or the tip of the finger. The result of such an accurate test was positive; no error could be detected.

The next examination was made with regard to perception of movements of individual fingers. The patient's eyes being closed, extension, flexion, and rotation of each segment of the fingers were performed. With the exception of the forefinger, the entire hand was found to be normal. Mistakes were made in flexion of the forefinger—a slight flexion was taken for rotation, forced flexion for slight flexion—extension movements were perceived normally. Similar movements were given the entire hand at the wrist. Their appreciation was correct.

I then proceeded to the test for form (stereognosis) of objects, their consistence, also the material of which they were made. An eraser, glass stopper, small glass bottle, small scissors, steel pen, lemon, small button, and a silver half dollar were the objects tested. The form, angularity, consistence, and material of which they were made were all recognized correctly and promptly. But when the nature of the objects and their names (symbolia) were tested, some errors were committed by the patient. Scissors, bottle, lemon, eraser, and the half dollar could not be recognized, and were taken for something else, while the other objects were detected. The latter were recognized only when they were held between the thumb and forefinger, but when placed on the palm and palpated with the last three fingers, the patient was unable to tell their nature and name them. The patient was kept on iodides for a period of four months. During that time a systematic reeducation of the use of his fingers and recognition of objects were kept up regularly and persistently. At first he improved—a number of objects were repeatedly placed in his hand and he gradually learned their nature. While the motor power of his hand and individual fingers was almost normal and the grip was very good, although he could find with the thumb and forefinger the button of his coat and the corresponding buttonhole, he nevertheless was unable to insert the button into the hole; a numbness, he said, in the two fingers preventing him from directing the button to the hole and finishing the act.

The treatment was discontinued by the patient and a month later he presented the following condition: The just mentioned numbness of thumb and forefinger remained the same. Patient was unable to feed himself, write, dress himself with the right hand—objects dropped out of his hand. The power, however, of each finger and hand tested by squeezing, pressing, and resisting proved to be normal. As to sensations, touch, pain, and temperature were normal. With the naming test we found that while on the first examination there was no involvement of the hand except the palm, now the patient made mistakes in recognizing spots touched on the palmar surface of the middle finger. The same can be said about Volkman's looking procedure except that here slight mistakes were made, not only on the forefinger, but also on other fingers (palmar surface). The perception of movements was now also somewhat more involved than before; in addition to the forefinger, the middle finger was equally affected, namely, a slight flexion was taken for rotation and forced flexion for slight flexion. Recognition of form (stereognosis) and nature (symbolia) of objects was somewhat more affected than upon the first examination. Among the objects used the first time a pen was taken for a pin; every other object was appreciated precisely in the same manner as described above.

To sum up the various sensory phenomena in my patient we must say that the first and last examinations differed slightly, that the superficial sensations, viz., touch, pain, and temperature were totally preserved, that the deep sensations were altered. The latter consisted of the following phenomena: The pressure sense was normal. The localization sense was only slightly altered for the fingers when tested with the naming and looking procedures, but the spacing of two points on the thumb and forefinger was decidedly altered. The localization sense of the palm was much altered. Perception of movements was slightly involved for the forefinger. Stereognostic sense (form) was intact, but the recognition of the nature of objects (symbolia) while not entirely lost, was, nevertheless, deficient. Before going further into the subject one can draw this inference, that deficiency in appreciation of the nature of certain objects is not dependable in this case upon the appreciation of their form and shape, but is apparently in relation with other forms of sensations.

Case II.—Mrs. S., middle aged, complained of difficulty in appreciating the nature of objects when held between the thumb and forefinger of the right hand. The condition existed three months before she consulted me. The onset of the disorder was not preceded by any special symptom that could attract the patient's attention. One day while at her housework she observed the phenomenon. Her previous health was good. She is a mother of several children, and has had no miscarriages. Hysteria was absolutely eliminated. A close examination showed total absence of patellar tendon and Achilles' tendon reflexes. The eye examination showed a distinct Argyl-Robertson pupil on both sides. The condition was, therefore, highly presumptive of tabes, although there was no pain, ataxia, sphincter disorder, or any other symptom of tabes. Bernacki sign, however, was present on both sides. Examination of the affected hand showed good motor power and no ataxia. The test for various sensations was made precisely according to the plan given in the first case. The following result was obtained: Touch with cotton over the palmar and dorsal surfaces of the thumb and forefinger was not perceived, but touch with a heavier object was well recognized. When the middle finger was touched, she said it was the ring finger. The middle of the palm was anesthetic. The re-

mainder of the hand on both surfaces was normal to touch. Pain and temperature senses, position of the fingers, and perception of movements were normal over the entire hand and individual fingers. Pressure sense was somewhat altered. Different weights were placed successively on the thumb and forefinger and results compared with those of the opposite side. Light weights were hardly or not at all noticed on the right. Localization sense determined with the looking procedure was intact, but with the naming and spacing tests proved to be faulty. Thus naming was erroneous on both surfaces of the last phalanges of the thumb and forefinger, but not on the other phalanges of the same digits. One point of the compass was felt instead of two when applied at a separating distance of an inch on the thumb and forefinger. The remainder of the hand was normal. Further examination revealed that when a thimble, small bottle, paper box, and a cork were placed between the thumb and forefinger, the patient could well distinguish the shape, form (stereognosis), material of which they were made, but could not in a single instant determine the nature of the objects and name them. When very small objects, such as shirt button, a pebble, were put between the affected digits, the patient was unable to recognize their shape (astereognosis) as well as their nature (asymbolia). On the other hand when she was allowed to manipulate the objects with all the five fingers of her hand, she could promptly name every quality of objects and name them whether they were very small or large in size. Because of the presumption of tabes in this case the patient was placed on iodides in gradually increasing doses. Four months later she was reexamined and her condition found totally unaltered in every detail.

Case III.—Man, thirty-three years old, cigarmaker by occupation, gave the following history: For the last five months he had had a numbness in the fingers of his left hand which would come and disappear. Five weeks ago he suddenly felt dizzy, had nausea, and rapidly a paralysis of the left hand developed. Four days later he suddenly lost his speech and the lower half of the left side of the face became drawn towards the right. Two hours later the speech returned. On the day of the examination he complained of severe headache especially in both temporal regions. The left arm and forearm had preserved their power, but the grip of the hand considerably weakened. When the patient was told to stretch out his left hand, he could not do it in a straight line—the fingers had a tendency to flex and the forefinger remained on a higher plane than the other fingers. There was a distinct ataxia in the left hand—when he was asked with eyes closed to place his forefinger or any other finger on his nose, he was unable to find the place, and when accidentally he found it, he did not know whether he was correct or not.

The patient's previous history presented nothing special worth mentioning. His heart showed a slight presystolic murmur at the apex. The eyes showed a low grade choroiditis at the periphery of both fundi, otherwise the latter were normal; the pupils reacted promptly and freely to light, accommodation, and convergence.

An examination for superficial and deep sensations of the left hand gave the following results: Touch with cotton was completely lost on the palm and dorsum of the hand and on the fingers. Above the wrist on the forearm the touch sense was preserved except on the ulnar side where it was lost. Pain sense was felt on the hand, wrist, and forearm. Temperature sense was totally abolished. The localization sense tested by the naming, looking, and spacing procedures was markedly deficient. Thus when the thumb was touched, he indicated the palm, etc. The pressure sense was impaired; objects placed in the left hand appeared to him much lighter in weight than in the right hand. Position and perception of movements were equally deficient in the hand and fingers. For example flexion or extension of the fingers was interpreted by him erroneously. When various objects were placed in his hand, all he could tell was whether they were hard or soft, but he had absolutely no knowledge of their form (astereognosis), dimensions, or material of which they were made. He possessed absolutely no knowledge of the nature of the object and could not name them (asymbolia). An energetic course of treatment with iodides during a period of two months failed to improve the patient's condition.

A careful analysis of the sensory phenomena in each of the three cases leads naturally to the consideration of the following questions: Is there a relationship between the superficial and deep sensations on one hand, stereognosis and asymbolia on the other? Also are the two latter phenomena related to each other or else are they independent functions and represented in the brain by isolated centers? In the first of our cases the superficial or elementary sensations were totally intact, if under this name we understand only touch, temperature, and pain. The deep sensations which are complicated and comprise pressure, muscular sense, localization, spacing, recognition of form (stereognosis), and movements, were affected in our patients. Perceptible alterations we found only in regard to spacing of two points in the thumb and forefinger, but very slight changes were seen with regard to localization by all the fingers through the naming and looking procedures; perception of movements was also slightly altered for the forefinger. The stereognostic perception which consists of recognition of the form of objects (*στέρεον*) is a complex cerebral phenomenon and to its proper and normal manifestation several sensory elements must contribute. We know now it is not based exclusively upon the elementary senses (touch, pain, and temperature), but mainly upon deep and complex sensations, such as pressure, movements, and spacial sense. Clinical observation shows that touch, pain, and temperature may be totally preserved, and still the form, shape, consistence of an object may be entirely unrecognized. Wundt ("Grundzüge der physiologischen Psychologie," 1893) makes the sense of innervation play an important rôle, which means the sense of degree of muscular contraction just necessary for a movement or for an attitude. To all these elements may be added sense of resistance and perception of position. While certain writers include all these senses as indispensable in formation of ideas of form of objects, others attribute to pressure alone, others to movements, and still others to spacial perception the most important rôle. There are cases in the literature in which loss of impairment of knowledge of form is in direct relation to the loss or impairment of any one of several or else of all the above deep and complex sensations.

Applying this information to our first case we find that the primary identification of an object (astereognosis) is not at all dependent upon the superficial sensations (touch, pain, and temperature) as

they are here perfectly preserved, neither it is in direct relation to the deep sensations. Among the latter the spacial sense particularly was emphasized by some writers, such as Hoffman, by Bonhoffer and others. In my case while the perception of movements and localization sense were only slightly altered the spacing sense was particularly affected. And yet the perception of form of objects was absolutely intact. In the second of my cases, touch was the only superficial sensation that was very slightly affected. Pain and temperature were normal. Among the deep sensations position and movements were unaltered, but pressure sense was somewhat changed, localization by means of the naming and spacing tests was deficient, one point of the compass was felt instead of two when the separating distance was an inch. These errors concerned only the thumb and forefinger. The spacing test upon which many authors lay so much stress for appreciation of form of objects (stereognosis) was similar to the first case, especially affected, and still the stereognostic sense was perfectly preserved. The patient was able to recognize the shape, consistence, and material of which the objects were made. One must, however, add that the ability to recognize form was good only for objects of more or less large size, such as small bottles, paper box, thimble, cork. The form of very small objects, such as shirt buttons, pebbles, and the like could not be appreciated by the patient.

It is therefore evident from the two cases that stereognosis is not always dependent upon the other sensory perceptions, deep or superficial. In the third case the perception of form of objects was, if not in a direct relationship to the condition of the deep and superficial sensation, at least equally involved. The latter were markedly affected, except the pain sense, which was, however, increased. Touch and temperature were totally abolished on the dorsal and palmar surfaces of the entire hand and all the fingers. Localization, pressure, position, and perception of movements were all decidedly deficient. The primary identification of objects was totally abolished. Astereognosis was absolute. Patient had no knowledge of form, or dimensions of objects placed in his left hand. If we admit that stereognosis is dependent upon other sensations, its involvement was to be expected here. If, however, it is an independent phenomenon, all that can be said is that in the third case above reported all sensations were deeply affected.

Let us turn our attention to the other important part of our thesis, viz., recognition of the nature of objects and the naming (symbolia). In the first of my cases, as we have seen, the spacing sense of the thumb and forefinger was markedly altered and only very slight changes were observed in the other deep sensations. The stereognostic sense was totally preserved, but recognition of certain objects placed in the affected hand was deficient. In the second case also the spacing sense was markedly affected, other deep sensations were more or less deficient, stereognostic sense perfectly preserved for objects of certain size, but the patient was absolutely unable to name them when placed between the thumb and forefinger. In the third case all the sensations were deeply affected, astereognosis was present, and the patient was unable to recognize the nature of objects as well as to name them. From the first two cases we must conclude that symbolia is certainly not dependent upon stereognosis. A patient may appreciate form, shape, dimensions of an object, and still not be able to recognize it. But here the asymbolia is present alongside of other deep sensory disturbances, such as spacing, pressure, localization. Can one say that the former is dependable upon the latter?

There are cases in the literature in which gross changes in the deep and superficial sensations existed together with asymbolia, there are others in which asymbolia was absent and still others in which asymbolia coincided with extremely slight changes in other sensations.

Among the most recent observations can be mentioned that of Raymond and Egger (*Revue Neurologique*, 1906, p. 371) and of Rose and Egger (*Semaine Médicale*, 1908, p. 517). In the first of these cases the superficial sensibility was intact, the deep sensibility was only very slightly involved, viz., pressure, vibration, position; the compass measurements was also very slightly involved. The patient could perfectly well recognize form and consistence, and could tell whether an object was smooth or rough. But asymbolia was complete. A number of objects were placed in the patient's hand and she could not tell the nature of any of them. Two years later the above sensory disturbances were still present, but asymbolia disappeared completely; the patient was then able to recognize objects.

In the case reported by Rose and Egger a man of 33 presented a slight motor weakness with a very slight ataxia in the left arm. All forms of sensations, deep and superficial, as well as stereognosis, were perfectly well preserved, and still the patient was unable to name objects placed in his hand. These two cases with my first two cases prove, I believe, conclusively that neither the stereognostic perception nor the faculty of recognizing objects (symbolia) are always dependent upon other forms of sensations. As to stereognosis, it was intact in Raymond and Egger's case in spite of slight changes in other forms of sensibility; it was intact in my first two cases in spite of pronounced alterations in other forms of sensibility. Asymbolia was present in Rose and Egger's case in spite of complete integrity of all possible forms of sensibility. It was present in Raymond and Egger's case when very slight changes occurred in some of the forms of sensations. The latter was so slight that they could be considered negligible, but then two years later asymbolia disappeared when the slight sensory disturbances still remained the same. In my first two cases asymbolia was present together with changes in the deep sensations, except stereognosis. That asymbolia is in no relationship with astereognosis can be seen from the two cases reported by the French authors above mentioned and also from my two observations.

A priori one may admit that recognition of form and dimensions of objects as well the idea or the concept of objects are based upon the harmonious association of all sensory images. All individual sensations, such as touch, pain, temperature, pressure, movements, position, attitude, etc., must be combined in order to give the proper idea of form and of nature of objects. Clinical experience, however, demonstrates, as seen from the present study, that stereognosis and symbolia are independent phenomena and that their relation to the elementary sensations is meager, that they consist of complex associative processes of the highest order, processes in which the well-known sensibilities play only a minor rôle.

ESOPHAGEAL DIVERTICULA*

By EMIL MAYER, M.D.,

NEW YORK.

ADJUNCT ATTENDING LARYNGOLOGIST, MT. SINAI HOSPITAL, CHIEF OF CLINIC EAR AND THROAT DEPARTMENT, MT. SINAI HOSPITAL DISPENSARY, CORRESPONDING FELLOW BERLIN LARYNGOLOGICAL SOCIETY, FELLOW AMERICAN LARYNGOLOGICAL ASSOCIATION, ETC.

This subject is presented for your consideration because of the difficulties that offer themselves in its diagnosis and appropriate treatment. A pouch or hernia of the esophagus at its posterior junction with the pharynx, called a diverticulum, may be due to pressure from within (over distension) or to pulling from without. The distension or pulsion diverticulum occurs most frequently; usually in males over forty years of age and in the following manner: In consequence of some local influence the muscular fibers of the esophagus became weakened, the constant pressure of the act of swallowing now distends the tube, a sac is formed in which food may remain after deglutition. The weight of these masses distends the sac, and it is dragged down behind the esophagus between it and the vertebral column.

Traction on the anterior wall due to an inflammatory swelling of the parts immediately adjoining the esophagus causes the form known as pressure diverticulum. The symptoms are those of obstruction to the swallowing of food, and upon the severity of this condition depends the amount of emaciation that may be present. As illustrating the difficulties in the way of diagnosis, the recent report of an "Iconoclastic revision of a classical case of diverticulum of the esophagus," by C. D. Spivak, of Denver, Colorado (*New York Medical Journal*, March, 1910, page 543), may be cited. This case is quoted as classical in all the text-books on surgery, was originally recorded by Bychowsky, and was claimed to be unique in that the diverticulum was not at the junction of the pharynx and esophagus, but at its lower end. The writer then marveled frequently upon the continued vitality of the patient in spite of the serious nature and locality of his obstruction. The trouble began when the patient was twelve years old, and it came on suddenly; at first all food came back as soon as ingested, later he could eat in comparative comfort, but would vomit a quantity of food after meals. For six years he lived on tea and large quantities of sugar. A piece of meat that he then ate stuck in his throat, being vomited out at the end of the third day. A celebrated gastroenterologist now treated him for over a year, unsuccessfully. He was then under Bychowsky's care for a year and a half, the latter presenting his findings based upon these observations. The patient declined the offers of celebrated surgeons to have an operation performed. Because of the unique character of his condition the freedom of the clinics of various cities was freely offered him. In Paris he found himself better able to swallow by drinking wine and water with his meals. Coming to the United States, beer took the place of wine and finally necessity drove him to water, and he soon found that water of a proper temperature, slowly sipped, enabled him to swallow many different foods. Fourteen years after the commencement of his trouble, this patient came to Colorado on account of lung trouble, entering the Sanatorium of the Jewish Consumptive Relief Society, at Edgewater, Colorado, where he came under the observation of Spivak, whose examination showed that tubes introduced came to a standstill at the same distance from the incisors, finally, however, when a cable was inserted to which a small olive point was soldered, it readily glided into the stomach. The diagnosis of a stenosis on the functional basis of cardiospasm was now made. The patient died and no diverticulum was found at autopsy. Commenting upon this, the writer says that this case became the basis for a new classification of the pathology of the esophagus and is quoted and referred to in all text-books and monographs on the subject. It is, in short, a case which became classic and is found fourteen years after to belong to the category of "such stuff as dreams are made of," and now offers ample excuse for reporting.

With the difficulty of deglutition, the patient notices that the boluses of food seem to lodge in the throat and occasionally firmer portions of food appear in the mouth many hours after eating, without any eructation or vomiting. This condition may continue for years possibly undiagnosed, and, as happened in my own case, the patient was told "not to bother; it was merely a nervous or hysterical manifestation." When the pouch is large, the food not only remains in it, producing a fetid breath, but emaciation which may lead to starvation occurs, and ulceration or inflammatory disturbances exist in the pouch consequent upon the presence of decaying food. The duration of the symptoms may be of valuable aid in the differential diagnosis between cancer and diverticulum, but it must be borne in mind that a carcinoma may develop in the pouch.

In an article on the routine examination of the esophagus, Charles M. Cooper of San Francisco (*American Journal of Medical Sciences*, February, 1910, page 221) presents many valuable points. "Given a history of disturbance of deglutition, we must bear in mind the various conditions which may be causal factors, a diverticulum, a tumor from within or without, an aneurysm, a cicatrix from swallowing a caustic, etc., hence the examination should be conducted in a routine manner and the esophagoscope used last of all. The history is carefully noted, the larynx examined for any cord paralysis or abnormality in position of the larynx, the throat massaged from below upward to see if the saliva which does not pass the constriction remains in the pharyngeal slit, and the patient is given fluid to swallow and later some bread. If in shaking the throat of a patient who has a diverticulum, we can produce a succussion sound, or if by giving the patient two or three bismuth capsules, they can be massaged from the lower part of the neck into the pharynx, a diverticulum may be discovered. The laryngeal picture may now have changed after deglutition and hence a second examination must be made. The pulse should be examined also, as the distended pouch may compress the deep vessels. The *x*-ray examination should now be made. This should be done anteroposteriorly. A mixture of two or three teaspoonfuls of equal parts of bismuth subcarbonate or oxychloride and sugar of milk made into a paste with water is now given and a radiograph taken. If the pouch is below the level of the aortic arch, the patient is placed in the right anteroöblique position. If a carcinoma is suspected, bismuth capsules are given and these may be readily

*Read before the American Laryngological Association at its Thirty-second Annual Congress in Washington, May, 1910.

seen lying above the growth." The writer feeling that the retention of bismuth in the pouch may act as an irritant subsequently, as it is not so readily removed, used the following expedient: A soft rubber tube firmly tied, was filled with shot and introduced warm and oiled gently to the point of constriction, and an excellent plate was the result, one which required no interpreter. If our examination shows an aneurysm to be present, no esophageal tube should be inserted; if a cancer of the esophagus exists, the esophagoscope may be used with removal of such portion of the growth as may help to make the diagnosis clear. The sound or bougie should precede the esophagoscope, which should be the last method. The stomach should be empty; the dilated esophagus washed out, one-quarter grain morphine with 1/100 grain of atropine given a half-hour previously, no sound passed for twenty-four hours, and the structures well anesthetized with 10 per cent. solution of beta-eucaine in adrenalin and the examination made with the patient sitting or in the left lateral or dorsal postion. Cooper uses the Einhorn instrument, watches its passage over the epiglottis and into the pharyngeal slit; the mandrin is then introduced and the instrument carried past the inferior constriction when the mandrin is withdrawn and the passage of the instrument carefully watched.

H. S. Plummer (*North Western Lancet,* June 15, 1909) reports six cases of diverticula occurring in the practice of Dr. C. H. Mayo. For diagnosis he gives much credit to the method of using a silk thread as a guide as first proposed by Mixter.

Ballooning the esophagus should be mentioned when referring to diagnostic methods. S. Kelen (*New York Medical Journal,* February 23, 1907, page 345) introduces a sound with an airless bladder into the esophagus, this is distended until the patient feels the distension; by means of connecting tubes the exhaust air is measured. H. P. Mosher (*Transactions of the American Laryngological Association,* 1909, page 363) introduces an oval tube with transparent plug, pressure on the bulb distends the pouch, whose walls thus stand out clearly.

The need of careful routine examination cannot be too strongly emphasized, the one method should follow the other in the manner aboe described for undue haste and forcible methods might readily lead to disastrous results, as in the case of aneurysm, and by following this plan the patient becomes gradually trained to the method finally used.

Treatment.—Where the diverticulum has not occasioned any symptoms beyond that of mild distress, we may content ourselves with occasional washing out of the diverticulum and care as to diet. Where, however, emaciation exists, the diagnosis having been firmly established, radical operation may be performed with success. DeWitt Stetten, New York City, has recently presented a monograph on the radical extirpation of pharyngo-esophageal pressure diverticula (*Annals of Surgery,* March, 1910, page 301). Whether a previous gastrostomy should be done or not, must be decided for the individual case, but enough information is at hand to show that the operation for pharyngoesophageal diverticulum is readily performed and reasonably safe. Stetten has collected statistics of 60 radically operated cases; of these 50 were cured and 10 died, a mortality of only 16.6 per cent. In Stetten's own case, that of a man aged sixty-five, the patient, who had a history of interference with deglutition of over two years' standing, was much emaciated and cancer of the esophagus was diagnosed. Gastrostomy was performed. The patient did so very well after this operation, tubes at times entering the stomach, that the diagnosis of cancer was questioned and an x-ray examination was then made, using bismuth paste, and the obstruction shown to be a diverticulum. This was successfully operated upon and the gastrostomy wound was allowed to heal. These recent articles contain such full references to the literature of this subject that the writer deems it unnecessary to present them here.

The following case, mentioned in discussion of the symposium on diseases of the esophagus at the annual meeting of this Association in 1909, is here recorded with its subsequent history. On April 1, 1909, a clergyman, aged fifty-six, consulted me because of a feeling of obstruction in his esophagus, which had existed for over three years. He could recall that a long time previous to that, upon bending over he could bring up grapes swallowed hours previously, without any eructation or vomiting. More recently he noticed that while there was no obstruction to part of his food, he found thorough mastication advisable, and from time to time would find food to appear in his mouth that he had ingested some hours before. There was no pain, no sense of fullness, no vomiting, and no emaciation. Slight hoarseness at times was always relieved by appropriate laryngeal treatment. An examination showed the right middle turbinate to be hypertrophied, mucous membrane of the larynx slightly engorged, cords functionating properly, liquid was readily swallowed. A large soft stomach tube was arrested eight inches from the mouth and as it was withdrawn a piece of bacon that had been swallowed four hours before was found in the mouth. An x-ray examination subsequently undertaken in the manner above described, showed the obstruction to exist at the junction of the pharynx and esophagus. A soft stomach tube passed the constriction easily, solid bougies were carefully passed and no blood followed, no discomfort, and no vomiting. A diverticulum was diagnosed which was washed out; this was repeated a few times, but nothing further was done. A year has elapsed since this examination was first made and the patient reports that he is able to avoid trouble with his throat by constant care in keeping his diverticulum free from accumulations. He is very careful to evacuate this diverticulum upward after eating or drinking anything so as to alleviate the unpleasant sense of fullness in that locality. He can then go out and use his voice without distress or any unpleasant results. He has not been compelled to cease from his usual vocation at any time during this year. Unless other symptoms arise, further interference is not deemed advisable.

From a consideration of this subject the writer presents the following conclusions:

1. The examinations should be conducted in a routine manner, the esophagoscope being used last, bearing in mind always the danger of a rupture of a possible aneurysm.

2. In making the examination with the x-ray, the introduction of a soft tube filled with shot may take the place of bismuth.

3. Esophageal diverticula may be readily diagnosed.

It may be of interest before presenting the final conclusion to quote from that model text-book of Von Ziemssen (Disease of the Esophagus, page 51, American Edition, 1878), "The radical cure of diverticula by operative procedure from without is at present one of our vain wishes; yet we should hope that even this operation conducted on Lister's plan might at some future day be performed without danger." It is, therefore, with the greatest gratification that we can now say that that wish is fully realized and gladly present the final conclusion:

4. Modern surgery offers much hope for these patients.

25 East Seventy-seventh Street.

NASAL OSTEOMA.

REPORT OF CASE; OPERATION.*

By J. H. GÜNTZER, B.Sc., M.D.

NEW YORK.

ASSISTANT SURGEON MANHATTAN EYE, EAR AND THROAT HOSPITAL; ADJUNCT PROFESSOR OF OTOLOGY, NEW YORK POLYCLINIC.

Nasal osteomata are less frequent than the osteomata of the accessory sinuses. Of the face skeletal osteomata, those of the nose only make up about 33 1-3 per cent. according to Haas[1], who has collected sixty-three cases affecting the nose and the accessory sinuses, of which twenty-one were nasal.

Nothing is known of a definite etiology, only hypotheses having been advanced for the causation of these osteomata. Trauma probably plays a less important part in their causation than was formerly believed, Bornhaupt[2] finding only six cases with traumatism as a causal factor in fifty-seven cases. Usually slow in growth, their beginning, very likely, dates to early life, since 54 per cent. occurred before puberty and 87 per cent. before the thirtieth year. The ages of the reported cases of osteomata ranged from thirteen to sixty-five years. As to sex the cases seem almost evenly divided, a few more in the male than in the female.

The histopathological origin of these bone tumors is still *sub judice;* Virchow[3] says that an osteoma of the accessory cavities of the nose which is covered by mucous membrane must originate from bone itself. Rokitansky[4] claims they originate from an enchondroma. Cloquet mentioned by Haas thought "the osteoma a direct ossification of mucous polypi, having found a polyp-like mass contained in a bony shell, and in another case he observed directly the opposite, viz.: ossification in the center of a mucous polypus." Tillmanns[5] reasons "that in all the accessory nasal cavities, respectively, in their ramifications, remains of the chondrocranium are found for a relatively long time, and he assumes that these cartilagenous remains may be the point of origin of the osteoma, and that the nasal osteomata and those of the accessory sinuses are probably developed from an enchondroma and later became ossified: the periosteal development is probably an exception, and this condition is favored by the slow development and the clinical course, since these osteomata form at an early age and grow for 10, 20, and 30 years; in a few cases quick growth was noted, viz., 1, 2, and 3 years or even in 4 to 7 months an osteoma had reached visible growth.

Osteomata are grouped by Ziegler[6] with the chondromata, angiomata, fibromata (nerve and skin fibromata), sarcomata, and adenomata, tumors which arise from some localized predisposition of the tissues of a distinctly congenital nature, and these have the distinguishing characteristics that they may be inherited.

While there is great variance in the views here cited, it may be assumed, owing to the fact that no osteoma in this region has as yet been found containing any trace of cartilage, that an osteoma of the nose or accessory sinuses is not an ossified enchondroma, but rather a new formation from the periosteum and probably of a congenital nature.

The frontal sinus seems to be the place of predilection for the osteomata of the accessory sinuses. Bornhaupt tabulates their situation in forty-nine cases, as follows: Frontal sinus in 23 cases, ethmoid labyrinth in 11 cases, antrum of Highmore in 10 cases, and the ethmoid and sphenoid sinuses in 5 cases, and of these forty-nine cases, thirty-four originated in the ethmoid, although an osteoma may arise from the frontal, lacrymal, or nasal bones, the nasal process of the superior maxilla, the turbinates, etc. In most instances the point of origin of these bone tumors is difficult to demonstrate, the weak connection with the nasal skeleton is so easily destroyed in operative manipulation, or, by pressure atrophy or pus formation the pedicle may be destroyed and the osteoma become sessile or entirely free; and when free they have been termed by the Germans "dead" osteomata. In Tillmanns' case two "dead" osteomata were found in the left frontal sinus and a "dead" osteoma in the right nasal cavity. Fenger[7] described a large osteoma arising from the right ethmoid, mixed in characer, being to a minor extent of the "dead" variety, while the major portion was active or growing.

These osteomata may be single or double in one cavity and may be double and symmetrical, one on either side in the various sinuses or in the nasal cavities as in Stein's[8] case. Frequently they are multiple distinctive growths, being often found in more than one of the accessory sinuses. In some cases the osteoma sends off prolongations from its place of origin, one tumor occupying two or more of the accessory nasal cavities, as in the case related by Heymann[9] where the tumor extended above into the orbit, below into the antrum, laterally and behind into the ethmoid labyrinth. At times after the removal of an osteoma from a nasal cavity or sinus, with the lapse of a few years new osteoma formation may take place in some other accessory sinus; Haenel[10] reported such an occurrence. In Coakley's[11] case of osteoma both the right and left nasal fossa were occluded and the tumor seemed to arise from the inferior turbinate. Kammerer[12] removed an eburnated osteoma weighing about 72 grams from the right nasal fossa; it was attached to the frontal and ethmoid bones, involving the orbit and antrum and caused prominence of the zygoma. Helfrich[13] removed a nasal osteoma weighing 60 grams. Heymann reported one from the nose the size of a small walnut, and in another case a larger one, as described above, but gives no dimensions or weight. Tillmanns' two, from the frontal sinus weighed respectively, 24.85 grams and 7.6 grams, and the nasal osteoma weighed 47.1 grams. Fridenberg[14] reported an orbital osteoma of ethmoid origin weighing 100 grams. In Habermaas'[15] case the nasal osteoma weighed 60 grams and measured 8.5 x 4.0 x 3.5 cms. Sprengel[16] also reported an ethmoid osteoma which was 2½ cm. in length and 1¾ cm. in thickness, but gives no

*Read before the Section on Laryngology and Rhinology, New York Academy of Medicine, February 23, 1910.

weight. Haas gives the weight of a nasal osteoma removed by him at from 70-80 grams and measured 93 x 48 x 40 mm.

We have in the structure of these bone tumors the two usual forms, the hard or eburneoid and the softer or spongy form. In the hard variety the place of attachment is usually soft or cancellous. Their size and shape vary, sometimes being a distinct cast of the nasal cavity or of the affected sinus. The surface is marked with rugæ, irregular, and nodular, mostly covered with periosteum and mucous membrane. That oesteomata may grow to an enormous size was shown by Hilton's[17] case, a bony growth invading the antrum, which weighed 440 grams; others of great size have been reported involving the various accessory sinuses which will not be mentioned here, enough of a descriptive character about osteomata has been included in the foregoing general review.

Concerned particularly with the nasal asteomata, further discourse will be limited to these. The clinical history of a nasal osteoma is inconstant, this depending almost entirely upon the symptoms, which in turn are mainly contingent upon the size of the growth and the amount of pressure exerted on the neighboring parts. The most prominent symptom complained of is nasal obstruction, which may be partial or complete, unilateral or bilateral. The osteoma may entirely occlude the nasal cavity so that the smallest probe cannot pass between it and the septum. Both nasal cavities may be occluded with an osteoma in each or, where only one nasal cavity is occluded, in course of time the other side may become obstructed, due to deviation of the septum resulting from the growth of the tumor. Difficulty in breathing may be marked and in some cases it is impossible for the patient to assume a reclining position, and he is compelled to sleep in a chair.

The tumor has been known to fill up the nasopharynx, causing middle ear disturbances. Obstruction to the olfactory cleft may cause partial or complete anosmia. The voice may be nasal and one may have nasal discharge or stoppage. Epistaxis is common. Suppuration and ozena have been observed. The glands of the neck and beneath the jaw may be enlarged. Itching of the nose is a frequent symptom, Heymann claiming that every case of nasal osteoma has it. Pain is often complained of, its situation depending upon the site of the tumor and upon the parts undergoing compression, but usually located in the course of the trigeminal nerve. Vomiting and asthma may be reflex symptoms. Vertigo is sometimes annoying. Ocular disturbances, as photophobia, diplopia, exophthalmus, and epiphora are usually due to the pressure and encroachment of the tumor on the orbit. Externally we may have nasal deformity, displacement of the tip of the nose, boadening of the nose, tenderness, and swelling. Displacement of the nasal bones outward takes place and if marked may cause the appearance known as "frog-face". Perforations through the nasal bones or orbital walls have been recorded. Bulging downward of the hard palate has been noticed and some parts of the skeletal face may disappear by pressure atrophy.

The diagnosis of a nasal osteoma is not always easy, often being made only at the time of operative interference. In a nasal fossa occluded by a tumor, to try the consistence of the same by attempting to pierce it with a needle or trocar may help to differentiate an osteoma from a cystic turbinate or chondroma. Osteomata are usually immovable; this may distinguish them from calculi or concretions, which, as a rule, lie free and are yielding. Where the swelling is large and we have external deformity of the nose we must remember the malignant conditions; but this may also be caused by a benign condition. Transillumination may or may not show a shadow. In the *x*-ray we have a means of demonstrating the extent of the tumor, its situation, as well as its contour, and by this means can also secure a more rational operation or plan of treatment.

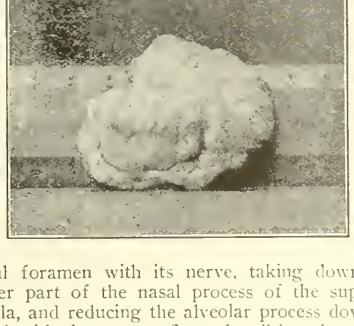
The prognosis is good in most cases unless the nasal osteoma invades the frontal or sphenoidal sinus from where it may extend into the cranial cavity and by pressure over the dura or by perforation of the same may cause a meningitis or brain abscess and so increase the gravity of prognosis.

The treatment consists in removal of the tumor *in toto;* the operative procedure advocated in all the reported cases embraces the laying open of the nasal cavity by an incision on the cheek along the side of the nose from the root down to the nasal wings, separating the nasal bones and the nasal process of the superior maxilla and a second incision outward on the cheek below the orbit, thus giving a wide aperture through which to deliver the osteoma. It is readily seen that this causes much scarring and may possibly lead to much disfigurement. The method followed by the writer in the case reported below is not original, it having been suggested more than half a century ago by Fergusson of England for partial excision of the upper jaw, yet its adaptation is new in the removal of a nasal tumor, and can be recommended in these cases on account of the small unnoticeable scar left after the operation, a not unimportant cosmetic consideration, and since by this method any amount of space can be gained without displacement of the nasal bones and without unnecessary incisions about the cheek or nose with their resultant disfigurement. The bone removed from the anterior antral and lateral nasal walls leaves no facial disfigurement.

Case Report.—Mrs. Bertha G., married, aged 37 years, came to the clinic of Dr. Jonathan Wright, at the Manhattan Eye, Ear, and Throat Hospital on June 19, 1908. She complained only of nasal obstruction on the right side and had neither pain nor discharge. The patient was robust and had always enjoyed good health. The right eye had been blind since childhood, due to an accidental knife thrust. The voice was flat. The face appeared somewhat broadened across the nasal bridge and malar region, but not to the extent of the so-called "frog-face". The right nasal cavity was found occluded by a large red mass resembling a cystic degenerated middle turbinate; posterior rhinoscopy revealed the mass filling up almost the entire right choana; the left nasal cavity was free but somewhat narrowed above by the septal deflection toward this side.

Under local anesthesia it was neither possible to make any impression upon the tumor with cutting forceps nor could a snare be engaged about the tumor mass. A fine probe could not be passed between the tumor and septum; the tumor was immovable. The patient was admitted to the ward on June 22, in order to break up and remove the tumor under general anesthesia. June 23, nitrous oxide gas and ether were administered and an attempt made to open with the chisel what was still thought to be a cystic turbinate with a thick wall.

After some work with the chisel and rongeur without effect, its ivory hardness became apparent and only at this time was a diagnosis of osteoma established. Attempts to move the tumor were unavailing. The operative procedure advised above was then adopted as follows: An incision was made through the upper lip in the medial line, the knife being carried alongside of the columna into the right nostril. Under the lip on the right side the first incision was extended backward through the gingivobuccal furrow for about two inches and the soft parts with the periosteum were elevated from the anterior surface of the superior maxilla and retracted upward and outward, raising the right half of the nose at the same time. With rongeur the junction of the anterior antral and the lateral nasal wall was ablated, partly preserving the inferior turbinate tissue and nasal mucous membrane, and so the antrum of Highmore was perforated and exposed. Penetration into the antrum was followed by a free gush of foul smelling greenish pus. Part of the anterior antral wall was removed and enough of the lateral nasal wall to expose the tumor to about one-half of its extent. The tumor could now be rocked slightly upward and downward, but was still wedged laterally. It could only be delivered after removing more of the anterior antral wall up to the orbital floor, necessarily sacrificing the infra-



orbital foramen with its nerve, taking down the greater part of the nasal process of the superior maxilla, and reducing the alveolar process down to a level with the antrum floor; by tilting the tumor upward, grasping it well posteriorly, and applying gentle force downward and laterally to the right, the tumor was delivered after considerable manipulation. The operation, lasting nearly three hours, was greatly hampered by free hemorrhage. It was now found that the middle turbinate, the ethmoid, and part of the sphenoid bone were absorbed by pressure atrophy and the floor of the orbit as well as the upper nasal septum (perpendicular plate of the ethmoid) in contact with the tumor were reduced to a mere tissue-paper thickness and in some places absorbed.

The mucous membrane of the antrum of Highmore had been converted into a brownish, thick, soggy, moss-like membrane, which was entirely excised. The nasal cavity and antrum were douched with a hot saline solution, the postnasal plug removed, iodoform gauze packing introduced into operative cavity, and the retracted parts brought down and sutured, silk being used for the lip and catgut for the gingivobuccal incision. The sutures on the upper lip were removed on the fourth day; primary union occurred. On the sixth day the patient was out of bed and feeling comfortable, except for some slight numbness of the right cheek. She was discharged from the hospital July 6, 1908.

The osteoma was 5.75 cm. long, 4.5 cm. wide, 3 cm. in thickness, 16 cm. in circumference, and weighed 53 grams. It was ivory hard in consistence, irregularly oval in outline, and covered by an investing mucous membrane closely adherent to the surface rugæ. A whorl-like indenture at one place probably indicated the point for a pedicle, its attachment to some part of the nasal cavity possibly having been destroyed during operative manipulation. (See the illustration.) A decalcified portion of the tumor showed the usual bone (Haversian system) construction.

In conclusion the following discursive points may be noted:

1. Had a diagnosis of osteoma been made prior to operation the *x*-ray would have been a valuable means of ascertaining the extent, location, and contour of the tumor.

2. To limit the amount of hemorrhage during an extensive operation about the face, a very vascular field, ligation of the external carotid artery may or may not control the bleeding. The complaint of not a few operators is that the hemorrhage in some of the cases is not always controlled by this ligation and that the ligation of the external carotid may be a risky procedure and be followed by formidable consequences, as was reported by Hertle[18], who cites a case where the external carotid was tied, with later formation of a thrombus of the internal carotid and multiple cerebral emboli as a result of which the patient died.

3. It is remarkable that an osteoma of the nose may grow to so large a size and exercise enough pressure to produce bone atrophy and absorption without causing any discomfort or particular clinical symptoms during an extended period of growth, and that the antrum of Highmore may be filled with pus and lined by deeply degenerated membrane without creating annoyance or symptoms.

4. That for the removal of intranasal or antral growths the operative procedure, as described in the removal of this nasal osteoma, gives a maximum of room for extirpation with a minimum amount of scarring and no facial deformity.

THE TREATMENT OF CHOREA WITH LARGE DOSES OF ARSENIC

(METHOD OF COMBY-FILATOV).

By G. B. HASSIN, M.D., and A. S. HERSHFIELD, M.D.,

CHICAGO.

INSTRUCTORS IN NEUROLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, UNIVERSITY OF ILLINOIS.

Of the numerous remedies offered for the treatment of chorea, the most popular is arsenic in the form of Fowler's solution (liquor potassi arsenici). Despite the frequent objections to the use of this remedy, it still remains the favorite and most effective method of treatment of chorea, provided it be given in large doses. The possibility of grave complications, especially on the part of the gastro-intestinal tract and nervous system, renders this method of treatment in many cases inapplicable. Therefore, many entirely abstain from arsenical treatment of chorea, resorting to antipyrine, salicylates, aspirin, bromides, etc. (Burnet, Lees, J. Allan).

In order to give the patient the benefit of large doses of arsenic without its unpleasant by-effects, Prof. Comby of Paris, France, advocated in 1896 the use, instead of Fowler's solution, the arsenious acid, (acidum arsenicosum As_2O_3) and in such enormous doses that almost seem incredible.[1] Comby's method consists in the following: He prescribes a solution of arsenious acid 1 : 1000, each teaspoonful of which contains just 4 milligrams or gr. 1/15 of arsenic. He takes 2½ teaspoonfuls, (℥ii ss) of this 1 : 000 solution, dilutes it with 6 tablespoonfuls of water and gives of the same a tablespoonful every 2 hours in a little milk. On the second day he takes 15 grams of the solution to 6 tablespoonfuls of water, on the third day 20 grams; on the fourth, 25; fifth, 30; sixth, 35; and on the seventh day, 40 grams, or 10 teaspoonfuls to a dose. Beginning with the eighth day, he progressively reduces the dose, by 5 grams, so that the entire treatment takes just two weeks, during which the patient takes about 6 grains of arsenious acid.

"If similar or equal doses of arsenic were given in the form of Fowler's solution," says Prof. Filatov, "we would have to start with 16 drops on the first day and give 64 drops on the seventh, while children rarely bear larger doses than 10 to 12 drops. Therefore, we must admit that arsenious acid is really better borne than potassium arsenite."

Comby's doses are too enormous, indeed, and in one of his cases, a girl of seven years old, he gave in eleven days 4 grains of arsenious acid. Comby himself says, that it is a formidable dose, which, however, all his patients were bearing admirably well.[2] This patient recovered from the chorea in twelve days, but four weeks after the treatment was completed and two months after the disease began, a paraplegia developed, accompanied five days later by incontinence of urine and feces, incomplete paralysis of the upper extremities, loss of tendon reflexes, complete reaction of degeneration of the muscles and nerves, and loss of sensibility. Comby diagnosed arsenical myelitis and confessed that "it is not wise to give such big doses of arsenic to small children, though many can stand such treatment without injury." The child recovered completely in three weeks.

In view of such serious complications, some authors, as Weill (Lyons) entirely abandoned Comby's method, some as Porot[3] reserve it only for very grave cases and exclusively for hospital patients, and some, as Filatov, Hutinel, and Babonneix, modified it to render this method of arsenical treatment safer.

Hutinel and Babonneix[4] begin with a teaspoonful of the 1 : 1000 solution of arsenious acid, increasing the daily dose only by 1 gram. They do not give this treatment to children below six years of age, and the maximal dose is only 18 grams, or 4½ teaspoonfuls. With such treatment they never had any disagreeable complications. Filatov's method[5] occupies the middle position between these two French methods. He gives to small children, four to six years old, half of a teaspoonful of the 1 : 1000 solution on the first day and to older children, Prof. Filatov gives a full teaspoon daily, increasing the initial dose by a half teaspoonful in younger, and a full teaspoon in older children. The dose is increased until the seventh day, after which it is decreased in the same proportion. The highest single dose will be for small children 3½ teaspoonfuls, and for older ones, seven teaspoonfuls or one-half of a grain of arsenic. Prof. Filatov treated, according to Comby and his modification, several cases of which he reported four.

In the first case, Comby's method was used and improvement was noticed on the fifth day, followed by recovery on the fourteenth day. In the second case, of two month's duration, Fowler's solution was first given and no results after twenty-five days of treatment. Then antipyrin (1 gram to a dose) was tried, also without results and was discontinued, followed by 1 : 1000 solution of arsenious acid according to Comby's method. The first dose was a teaspoonful and it was daily increased by a full teaspoon until the fifth day, when vomiting set in. For two days the treatment was discontinued and renewed on the eighth day with 4 teaspoonfuls as a single dose. On the following days the dose was gradually decreased and recovery followed on the second week.

In the third case, of ten days' duration, sulphonal was unsuccessfully used for four days and 1 : 1000 solution of arsenious acid started to be given on the fifth day, half a teaspoon as the initial dose, which was by the same amount increased until the eighth day, when 4 teaspoonfuls were administered. Improvement was noticed at the end of two weeks, and recovery after three weeks of the treatment.

In the fourth case marked improvement occurred at the end of the third week with a 1 : 1000 solution of arsenious acid. Prof. Filatov remarks that the results were the better, the earlier the treatment was begun, that all his patients gained in weight and that in old, protracted cases the solution could be given in smaller doses, half of a teaspoon to a dose, with the increase of the dose in the same amount up to 1 or 2 teaspoonfuls as a maximal dose, according to the patient's age. The treatment in such cases must not be conducted longer than two or two and a half weeks.

Despite the great authority of Comby and Filatov, the described method of treatment of chorea did

not meet with success, and in the literature and text books (Wollenberg, Oppenheim, Sachs) it is not even mentioned. Oppenheim[6] only points out that arsenious acid proved to be an effective preparation in the treatment of minor chorea, that it must be given in gradually increasing doses, beginning with gr. 1/60, and that Comby considers this drug very effective. Thiemich in Pfaundler-Schlossman's[7] voluminous text book describes Comby's method, but adds that it did not find any imitators in Germany. So far as we are aware, in this country Comby's method of arsenical treatment of minor chorea is entirely unknown, as the latest articles on this subject, Allan's for instance,[8] do not even mention it. Therefore, we deemed it necessary to describe this method *in extenso* and to report our experience with it in our private and dispensary practice.

Comby and Filatov had to deal with hospital cases, which, as is well known, may improve under the influence of rest and isolation, even without any medicinal treatment, while our patients have been treated with Comby-Filatov's method under ordinary circumstances.

Case I.—I. G., nine years of age, sick for three and one-half months. Twitchings in the left arm, face, and partly in the left leg. She could not use the left arm and things would drop from her hands. She had been treated for three and one-half months in various colleges of Chicago and by private physicians with Fowler's solution, 7 drops, as the maximal dose. I (Dr. Hassin) administered a solution of arsenious acid, 1:1000, half a teaspoonful for the first dose, gradually increasing this dose by a full teaspoonful daily. Vomiting appeared on the fifth day, but the child took the next day 5 teaspoonfuls and vomited again. The medicine was abruptly discontinued by the mother and the improvement which was marked on the fourth day, after 3½ teaspoonfuls of medicine, was almost complete after the fifth teaspoonful.

Case II.—Ch. R., seven years of age. A severe case of limp chorea. Very extensive twitchings in the shoulders, arms, and lower limbs. They were particularly extensive and severe during sleep, and the mother had to sit two nights near the boy lest he might fall out of bed. He could neither eat nor drink, as the food could not reach the mouth because of the twitchings. The disturbed sleep and lack of nourishment caused great emaciation in the boy, who became peevish and irritable. As he was getting worse from day to day, he was brought by the mother to the College dispensary on the fourth week of the disease. We gave him arsenious acid in 1:1000 solution (Rp. Acidi arsenicosi 0,12, Aq. destil. 120,0 S. ½ teaspoonful to a dose, gradually increasing by the same amount till 5 teaspoonfuls are taken). Marked improvement was noticed on the fourth day of treatment. The jerkings during sleep stopped entirely, and during the day they became very rare and noticed only upon voluntary exertions. The improvement was very marked and noticed also by the students. We purposely allowed the boy to play outside and at the same time we ordered the dose decreased in the same proportion as it was increased. In a few days the condition became aggravated and we administered the second course of arsenical treatment, with a teaspoonful as the initial dose, which we ordered to increase daily by one full teaspoon and instructed the mother to keep the boy as quiet as possible, taking him outside for short walks only. Again marked improvement, and as soon as we decreased the dose of arsenic the twitchings and jerkings would become more manifest. We, accordingly, had to renew the treatment with each aggravation of symptoms and altogether gave him four courses of treatment with 5 teaspoonfuls as the highest dose. After four weeks of treatment, the recovery was complete. We kept the boy home for six weeks longer without any arsenic having been given, and allowed him to go to school at the end of ten weeks since the beginning of the treatment. Now it is about ten weeks since we stopped the treatment and the condition of the patient is splendid. There were, so far, no relapses, no albumen in the urine, no cardiac disorders. On the fourth week of treatment, there appeared puffiness under the lower lids and a slight herpes zoster on the right side of the chest. Both disappeared within two days after the dose of arsenic was decreased.

Case III.—This was a case of general tic (Gilles de la Tourette's disease) complicated with chorea. B., aged eight years. Blepharoclonus, various choretic twitchings in upper limbs and in the muscles of the body. He would often emit a strange bark-like noise and would frequently repeat one word, "what." The mother claimed that, when on the street, he would swear at the boys, call them names, would get licked for that, and when asked why does he swear at the boys, he would say that he could not help it. The mother also reported that he frequently would bend himself on the street and touch the sidewalk, that when in the street car he would grasp her hat every other while. While the barking could be looked upon as a manifestation of laryngeal chorea, in combination with the regular, always of the same character and type, movements, as touching the sidewalk or the mother's hat in the car, with the echolalia, (repeating the same word "what"), and coprolalia, (swearing at the boys), it must be looked upon as manifestation of general tic, known as Gilles de la Tourette's disease. Besides, he also showed irregular, purposeless movements in the arms and other parts of the body, could not be kept quiet in school, where the teacher complained he "would touch everything and was nervous," which movements we had to refer to chorea and assume that the boy had a combination of Gilles de la Tourette's disease (general tic) with minor chorea. Therefore, we placed him on arsenical treatment according to Filatov's modification of Comby's method. We gave him as the initial dose ½ teaspoonful of 1:1000 solution of arsenious acid and ordered the dose increased daily by ½ teaspoonful until 5 teaspoonfuls were taken. The choreic movements and the laryngeal manifestations (the barking) considerably subsided after the fourth teaspoon and gradually disappeared entirely after four weeks of treatment. The blepharoclonus was not influenced, but the echolalia and coprolalia were no more complained of. The mother showed great satisfaction with the results of the treatment, which were also apparent to the students, and we permitted the boy to go to school, where they have had no more trouble with him so far. When the boy was improved we placed him on Fowler's solution, began with 1 drop a day and daily were increasing the dose by 1 drop until he had been taking 9 drops. Vomiting set in with the ninth drop and Fowler's solution was discontinued.

Case IV.—Aged eight years, typical chorea for

two weeks. Arsenious acid in 1 : 1000 solution, with ½ teaspoonful as the initial dose, increasing the dose daily by a full teaspoon. The treatment was carried out by a nurse of the Nurses Visiting Association that brought the boy to the College dispensary. Improvement set in on the fourth day, but the boy had to be placed in a hospital on account of his mother's severe illness. Here an ordinary treatment was used, the condition having become worse.

One of us (Hassin) has been using Comby-Filatov's method in the treatment of minor chorea for the last three years in his private practice, the treatment having been left in the hands of poorly trained mothers, and never was there any occasion to regret having used this method of treatment. No serious complications occurred, except vomiting in the Case I, or edema of the eyelids and herpes in the Case II, and we came to the conclusion that arsenious acid in the solution 1 : 1000 given in smaller doses than advocated by Comby are safer than Fowler's solution. This can be seen from the Case III, where a boy, eight years of age, could safely bear 5 teaspoonfuls of 1 : 1000 solution of arsenious acid, *i.e.* gr. ⅓ of arsenious acid, but showed symptoms of intolerance from 9 drops of Fowler's solution and this after his system has been somewhat used to the drug. The time of treatment is considerably shortened by using the acid, the improvement sets in very early, within a few days of treatment, and that it is due, exclusively, to the use of arsenic may be gathered from Case II, where the decrease of the dose would inevitably bring forth aggravation of symptoms and the increased dose an amelioration. How does arsenic work? By inducing poisoning of the central nervous system, as some think, or in some other way, we would not attempt to explain. The fact is that arsenical treatment of chorea with arsenious acid is a much safer method of treatment of minor chorea than with different arsenical solutions commonly used. It is true that complications are apt to occur, but complications are also possible with other drugs offered as substitutes for arsenical treatment. We do not consider it excusable to deprive chorea patients of the benefits of arsenical treatment on account of possible complications, just as we would not consider it wise to deprive syphilitic and other patients of the benefit of mercurial or iodide preparations only because complications are liable to occur. The by-effects of arsenical treatment can be greatly mitigated by using arsenious acid and can be avoided if attention be paid to the condition of the gastrointestinal and renal apparatuses.

THE ABSTRACTION OF CALCIUM SALTS FROM THE MOTHER'S BLOOD BY THE FETUS A CAUSE OF LARGE WHITE KIDNEY IN THE FORMER.

By JENNIE G. DRENNAN, M.D., C.M.,

CHICAGO, ILL.

Glomerulotubular nephritis, one of the saddest and most hopeless conditions in renal medicine has been considered when occurring during pregnancy, to be due to toxemia of obscure causation. Since the calcium salts are being shown to exert such an important influence in the metabolism of the body, it has occurred to me that this condition may be induced by such an abstraction of these salts from the blood of the mother by the fetus that a sufficient amount is not left in her blood for her own use. One of the functions of these salts in the animal body appears to be a union with neutral fat for the formation of lipoids or soluble fats. In this way fat may be kept in a state of continual solution, somewhat unlikely, or it may be deposited in certain tissues—its normal depots—and then by a process of dissociation the calcium may be reabsorbed and the fat remain as neutral fat. This fat is largely deposited in the subcutaneous tissues and in other situations where it may serve as a packing substance, as around the kidneys themselves, which, when imbedded in fat are held in position and protected from injury. Fat, so deposited, may, by a later combination with calcium salts, be conveyed to other parts of the body to serve, perhaps, as a food in a time of need—the case of the hibernating bear or the very sick patient who, unable to partake of much nutriment, comes through a severe illness. It would be most interesting to know if the patient, who survives a long and severe illness, has more available calcium salts to unite with the fat in these depots, which fat conveyed to the centers of metabolism may serve as food, and also to unite with the fat formed in organs and remove it from them, thus relieving their cells of a mass of useless material.

The kidneys normally contain no neutral fat; but by chemical examination about 23 per cent. of their solid matter is found to consist of fat, which has been there in a combined state. Now is it beyond comprehension that the epithelial cells of the glomeruli and tubules undergo normally a certain degree of fatty degeneration, the outcome of their work, and that normally this fat is combined with calcium and either cast off as an excretion or absorbed as a secretion and carried to other parts of the body? If the blood is poor in calcium salts this union cannot take place and consequently the fatty matter will remain in the cells as a fatty infiltration. In large white kidneys the epithelial cells are granular, opaque, swollen, and fatty, and fatty casts may be found in the urine. The latter is small in amount and acid in reaction, no doubt due to a lack of alkaline material. The fat, which should have been united with calcium to form soluble fats to be carried from the kidneys, remains in the cells uncombined, and by its presence prevents the regeneration and continuance of functions of their cells. These patients have less neutral fat in other parts of the body. By some this has been said to be due to a transposition of fat from its normal depots, viz., the subcutaneous tissue, etc., to the liver and other organs in the tissues of which it may be

found; but I am inclined to think that this explanation is a case of putting the cart before the horse, and that its presence in these organs, and its absence from the subcutaneous and other like tissues is due to the fact that calcium salts are not present in sufficient amount to unite and form lipoids of the fat, the result of degenerative and other changes. Metabolism other than a degenerative process may form fat in the tissues and may be the means of conveyance from these tissues of this fat, which should be ultimately deposited as neutral fat in its normal depots. A patient with fatty infiltration of her cells cannot perform the functions of her body, and consequently a train of symptoms is established which is toxic in nature; toxemia being rather the result than the cause of the condition. The great deposition of fat in the elderly may be due to the increased fatty degeneration of cellular tissue, and to a free supply of calcium salts—not so much calcium being necessary for the growth of bones—and by the union of this fat with calcium salts, the resulting lipoids are formed and conveyed to the subcutaneous tissues, where the calcium is abstracted and the fat deposited as neutral fat. It is a fact that stout, elderly people are not usually those who have the greatest amount of fatty infiltration or degeneration of their organs, and this may be the reason. Absence of calcium salts due either to an insufficient amount in the blood, or due to an increased accumulation in the various tissues—the very brittle bones of elderly thin people—prevents a union of these salts with the neutral fat and, therefore, prevents the deposition of the latter in the subcutaneous or other tissues outside of these organs. The embedding of an organ in fat need not interfere with its function, but may rather maintain it in its normal position and prevent a ptosis with its aggravating symptoms and interference of function; but an organ whose tissues are themselves the seat of fatty changes is one which cannot properly functionate. There is a tendency in old age for calcium to be deposited in lesions and this may be another source of the scarcity of calcium salts in the blood for union with the fat produced in the cells of the organs.

During pregnancy the kidneys are doing an extra amount of work, for the mother must excrete the waste material of the fetus as well as her own. Under normal conditions she is perfectly able to do this, but under conditions of malnutrition, due either to poverty or an inability to partake of proper nutriment, she does not consume the necessary amount of calcium salts for the developing needs of the fetus, for her own various tissues and for the formation of lipoids and for possibly other combinations of which as yet nothing is known, as this study is only in its infancy. Under this interpretation calcium salts are fat carriers. A moderate degree of fatty infiltration during pregnancy may possibly exist without causing any marked symptoms, but if more than moderate in amount it is a source of great danger at the time to the patient and may be the cause of an incurable condition later on. Finally, the epithelium being completely degenerated, anuria will result with its attendant symptoms and death.

SUMMARY.

1. Normally, cells undergo some fatty degeneration.

2. Normally, calcium salts unite with this fat to form lipoids in which form it is conveyed from the organs to other situations, and after the abstraction of its salts is deposited there as neutral fat.

3. In pregnancy there is an increased production of fat due to the increased work on the part of the renal epithelium.

4. In pregnancy there may be a decreased amount of calcium in the mother's blood due to its abstraction by the fetus.

5. Therefore, the fat in the renal epithelium is not combined with calcium to form lipoids and consequently remains there as neutral fat, causing an interference with the function of the cells.

PRECAUTIONS IN LABORATORY AND MORGUE THAT LESSEN THE DANGER WHEN DEALING WITH PLAGUE.

By DONALD H. CURRIE, M.D.,

Honolulu, T. H.

Passed Assistant Surgeon, U. S. Public Health and Marine Hospital Service.

The precautions recommended in this article are those that we have been accustomed to observe while dealing with plague.

Precautions Recommended for the Necropsy Room.—This room should be fly-proof; the floor should be made of concrete and slope to the center, at which point there should be located a concrete-lined well, having connection with the sewer, but so arranged as to permit of the opening or closure of this connection from without. Before performing the necropsy the sewer connection of this well should be closed, and a pound of commercial lye placed in the latter. The necropsy table should slope to the center, where there should be an opening to permit the body fluids to pass into a gutter beneath the table, and from thence into a bucket.

On receiving the body the lid of the coffin should be raised and several ounces of chloroform poured on the body; the lid should then be replaced, and the chloroform allowed to act for thirty minutes to destroy any insects that may be present.

With his hands protected by gloves the attendant should then open the coffin and remove the clothing from the body. The nude body should then be placed on the necropsy table and sprinkled with a solution of bichloride of mercury (1 to 500) in order to render innocuous any discharges that may have soiled the body surface.

During the necropsy the surgeon should wear rubber overshoes, a long sleeved gown, and heavy rubber gauntlets, the latter having a canvas inner lining. The sleeves of the gown should be drawn down to the wrist and tied to the upper part of the gauntlet.

In performing the necropsy the surgeon's motions should be slow and careful to avoid the splashing of body-fluids as well as the danger of wounding himself. Should body-fluids be splashed upon any one present a compress of gauze soaked in a strong solution of bichloride of mercury should be applied to the point that received the infectious fluid—on no account should any attempt be made to remove such infectious matter by wiping, lest the contained bacilli be rubbed into the hair follicles.

At the end of the necropsy the surgeon should immerse the gloves in 1-500 bichloride solution, and then remove them without touching the soiled sides. After this the hands and face should be mopped over with some antiseptic solution, but all rubbing motions should be avoided.

Should the surgeon wound himself during the necropsy every effort should be made to encourage the injured tissues to bleed freely, after this the wound should be immersed in a solution of formaldehyde (1-100) and an immunizing doze of Yersin's serum should be administered as soon as practical. After the necropsy the body should be placed in a zinc-lined coffin, the latter filled with quicklime and closed.

The gauntlets, gown, and overshoes worn by the surgeon should be immersed in bichloride solution (1-500). All instruments employed during the necropsy should be boiled; the necropsy table and floor of the necropsy room should be sprinkled with quicklime, and several hours later the room should be washed down with a 5 per cent. solution of commercial lye. This solution of lye will drain into the central well where it should stand for twelve hours, and then be allowed to flow into the sewer.

Precautions to Be Observed in the Laboratory.—The laboratory should be insect- and rat-proof. The employees should receive definite instructions as to the precautions to be observed. One attendant should be made responsible for the absence of flies within the laboratory. If dead rats are being received for examination the trappers should bring them to the laboratory in covered buckets, each of which should have a small hole in the lid; this hole should be corked.

A laboratory attendant should receive the bucket from the trapper, remove the cork and place a funnel through the opening in the lid of the bucket, and fill the latter with an emulsion of kerosine and soap containing 5 per cent. of crude phenol. The cork should be replaced and the filled bucket allowed to sit for twenty minutes. At the end of this time the animals may be taken out of the bucket by means of long-handled forceps and placed in a solution of bichloride; this serves to wash off the emulsion and complete the destruction of the insect parasites of the rat.

When the emulsion has been washed off in the bichloride solution the animal is lifted out of the latter fluid by means of a pair of long-handled forceps, placed on a convenient-sized board and necropsied.

If the necropsy demonstrates that the animal is probably infected with plague its body, together with the board it was necropsied on, should be burned. If the crematory is outside of the laboratory, the animal before being taken from the laboratory should be covered with enough absorbent cotton to take up the fluids that issue from its incised body.

In inoculating laboratory animals with plague it is safer to employ the platinum loop than the hypodermic syringe; the latter instrument is only necessary in intravenous or intraperitoneal inoculations, and these latter methods are rarely necessary in the routine diagnosis of plague.

After inoculation a glass jar should be chosen, several inches of sawdust placed in the bottom of it, and enough food supplied to last ten or twelve days (one large cabbage will suffice in the case of a guinea-pig). The animal should then be placed in this jar, and the latter covered with a double thickness of cheese cloth which should be bound to the jar by means of a strip of adhesive plaster to prevent the escape of small insects. This cage should not be reopened during the life of the animal. If the animal is still alive after the twelfth day it should be killed with chloroform.

Attendants should be instructed to listen for a peculiar sound which the guinea-pig utters when suffering from pneumonic plague (this sound has more the character of a sneeze than of a cough) and which is more apt to be noted in animals in which the illness is prolonged beyond the tenth day. It has been our policy to destroy such animals as soon as this symptom was noted.

After the death of the animal chloroform is poured through the cheese cloth cover and allowed to act for twenty minutes. A small hole is then made in the cheese cloth cover, a funnel inserted, and the jar nearly filled with a solution of commercial lye (one pound of lye to three gallons of water). After this solution has acted for five minutes the cheese cloth cover should be removed and placed in the Arnold's steam sterilizer. The animal is then removed from the jar, by means of forceps, and placed in a strongly acidulated solution of bichloride of mercury.

The lye solution should be allowed to remain in the jar for twenty-four hours to permit this chemical to penetrate the sawdust, feces and unconsumed food of the animal. The jar should then be emptied of its contents.

The precautions to be observed in the necropsy of rabbits and guinea-pigs are identical with those described in the case of rats.

Weak Foot.—Steinhardt does not apologize for presenting such an apparently small matter. He defines weak foot as a state of weakness or partial or complete lengthening of the ligaments and the muscles that effect the union and support of the tarsal bones. The etiology is extensive; excessive use of the feet and badly shaped shoes are the principal factors. He makes the following classification: simple weak foot, weak foot with eversion and rigidity, deformed weak foot, flat foot with eversion and rigidity, traumatic flat foot, and paralytic flat foot. Complications are varicose veins and exostoses or chronic inflammation of the inferior epiphysis of the tibia. He divides the symptoms into subjective and objective. Prognosis is always good if properly treated. The chief prophylactic measure is the manufacturing of proper shoes. The treatment should be directed to the restoration of the arch of the foot.—*Crónica Médico-Quirurgica de la Habana.*

Hypothyroidism and Disthyroidism in Children.—Luigi Concetti describes a new form of hypothyroidism and disthyroidism, occurring in infants who are born of or nursed by mothers or nurses who have changes in the thyroid glands. The mothers show signs of hypothyroidism such as obesity, transitory edemas, disturbances in the heat sense and circulation, easy chilling, thinness of hair, vasomotor disturbances, instability of nervous system, vomiting, and slight resistance of toxemias. In the children we occasionally find the marked form of myxedema, but in general see slight and abortive forms. These children are retarded in growth, suffer from attacks of asthma, headache, eczema, general atrophy, or asthenia. When treated with thyroid therapy we find the conditions relieved, showing that the absence of thyroid secretion was in direct relation with the conditions found.—*Rivista di Clinica Pediatrica.*

Treatment of Extrauterine Pregnancy.—Elis Essen-Möller advocates an immediate operation in every case of extrauterine pregnancy that is diagnosticated. He bases his opinion on forty-eight cases of extrauterine pregnancy operated on by him with but one death. Immediate operation will save most of these patients, while the expectant treatment will result in many deaths from uncontrollable hemorrhage. There is never a moment when the patient is not risking her life from hemorrhage. The expectant treatment necessitates a later operation for hematocele or other complications in many cases, and this is done at a time when success is less likely than in the beginning. A convalescence which is long, and during which the patient must remain in bed, is the result. The statistics which are given to demonstrate the advantages of the expectant treatment are misleading because they contain many cases of false diagnosis. Immediate operation has no more risks than the later one, and no more than any other abdominal operation.—*L'Obstétrique.*

HOSPITAL INFECTION OF TUBERCULOSIS.

IT would seem to be a somewhat natural sequence that those in constant contact with individuals suffering from pulmonary tuberculosis should become infected with the germs of the disease more frequently than those who are not continually exposed to risk of infection. Among the medical men, nurses, and attendants in a hospital there are likely to be, if not more likely to be, as many predisposed to infection as in the outside world. This is a question which has, however, not yet been thoroughly investigated. At a meeting of the Royal Society of Medicine held in London on April 26, Edward Squire read a paper on hospital infection of tuberculosis, as exemplified by the records of the resident staff of the Mount Vernon Hospital, one of the largest hospitals for the treatment of the disease in England, for the past fifteen years. After referring to the fact that up to the present time this phase of the matter had been little considered, Squire stated that the inquiry, though supporting the view that the risk of infection in a well-regulated chest hospital was very small, showed a larger proportion of cases of probable infection than has been shown in the statistics hitherto published in England. It showed also that a certain proportion of cases of tuberculous infection would be overlooked if the individuals' accounts of themselves were relied upon solely, several unsuspected cases having been detected as a consequence of routine examination of the chest. It was, likewise, demonstrated that a comparatively large proportion of applicants for posts, especially on the nursing staff, exhibited signs of previous infection of tuberculosis, and it seemed probable that residence in general hospitals might be responsible for such infection, or, at least, for the diminished resistance which made infection possible. The inquiry was divided into two main divisions dealing with (1) the incidence of previous tuberculosis in those applying for posts at Mount Vernon, and (2) the evidence pointing to infection during residence there. Fourteen per cent. of the nurses and 8 per cent. of the maid servants, showed evidence on entry of previous infection. This was chiefly found among those who had previously resided in hospitals whether general or special; for while of those who had previously resided in hospitals nearly 20 per cent. showed signs of former tuberculosis, less than 10 per cent. of those who had never resided in hospitals showed such signs. The cases of infection which occurred while in residence were eight in number, being 2.5 per cent. of all who remained for longer than three months.

In the discussion that followed the reading of the paper, the fact was emphasized that infection of tuberculosis occurred not infrequently in the porters at chest hospitals who assisted in the postmortem room, and the general conclusion reached by the members at the meeting was that physicians, medical students, nurses, and attendants in hospitals were more liable to infection by tuberculosis than were individuals belonging to the general community. These findings, although based on limited figures, are as might be expected. It stands to reason that nurses, at any rate, and in England in particular, should be more subject to infection of tuberculosis than ordinary individuals. Nurses in England are women who, as a rule, first join a hospital when they are quite young. The work is mentally and physically trying and arduous. Their hours are long and rest is, in the nature of things, irregular. It can, therefore, be no cause for wonder that if not constitutionally strong, their powers of resistance become diminished. This statement applies to a lesser extent to the medical staff, medical students, and attendants. Furthermore, it is only reasonable to suppose that those who are constantly in the near neighborhood of consumptives should run more risk of infection than those who are not placed in such circumstances. It would be interesting if statistics bearing upon this matter could be obtained from the various large institutions for the treatment of tuberculosis in this country.

THE VALUE OF ATHLETICS.

THE rapid increase in the prominence of the part played by athletics in the life of the American and English schools and colleges during the past generation has been a fruitful source of polemics in newspapers, magazines, and comic papers, and has occasioned many serious discussions on the part of those whose duty it is to care for boys and girls during the formative periods of their lives. From reading the average newspaper account of college life, one would be inclined to consider that a modern university is merely an overdeveloped gymnasium, wherein the body is developed at the expense of the mind and the studies are sacrificed for the sake of the sports. Not infrequently, too, we are informed not only that the mentality of the student suffers, but also that in the present day enthusiasm for bodily prowess the physique is also injured; that the oarsman and the distance runner are developed to a high state of temporary efficiency, but that the strain thereby entailed results in their being more or less crippled and rendered less capable for the battle of life; that in a great number of cases the overwork of training is evidenced in later years by a weakened heart, and that more harm than good results from school and college athletics.

Within the past few weeks two important articles bearing upon this subject have appeared. In the *Edinburgh Medical Journal* for May, 1910, Burn-Murdoch, the medical officer of the Merchester Castle School, speaks strongly in favor of athletics in the life of the school and college student. Drawing extensively from published records, and from his own statistical studies, he shows that injury from systematic athletic exercises among school boys is rare indeed. Occasionally accidents occur, but these are no more common in athletic contests than in the irregular skylarking in which every healthy boy is bound to indulge. As to overstrain, this he found to be practically unknown in the schools in which athletics is prescribed as a part of the regular course, where the boys are examined by a competent medical advisor, and the work is graded according to each boy's physical ability. In the few cases in which there is a record of overstrain of the heart, it was found, in practically every instance, to have happened in a boy who had not received the preliminary examination and thus a pre-existing heart lesion had been overlooked. Harking back many years the author refers to Morgan's classical study of the later history of university oarsmen in which he showed that the longevity of this class of men was considerably greater than that of the average human being.

The other article by F. J. Born, medical examiner of the Yale gymnasium, appears in the *Yale News* for May 6, 1910. In this a comparative study is made of the size of the present senior student of Yale, as compared to Gould's statistics of the senior classes of Yale and Harvard made in 1864, when athletics was of less importance in both school and college life than it is to-day. From these it is shown that though the height of the present student is practically equal to that of the college boy of fifty years ago, his weight averages over sixteen pounds greater, his chest is 1.6 inches larger, and his expansion is distinctly increased.

These are but a few of the many interesting facts contained in the two articles showing the advantage of systematic athletics. The chief lessons to be drawn from them are that the increase in athletics during the past half century has tended to produce a larger, stronger, and more capable type of college man, that in order to obtain the best results the training should be begun early in life in the preparatory schools, that if proper medical supervision exists, and the boys, and the girls as well, are put through a systematic course of athletics, graded according to their size, strength, and physical fitness, the danger is negligible, that the healthy, strong body so produced tends to make a man more capable both mentally and physically to win the fight of the world, and finally that the physical training of the boy in school should be as much the care of his teachers as is the development of his mind or his character.

The Parasitic Origin of Pellagra.

Louis Sambon, the well-known Italian investigator, who is attached to the London School of Tropical Medicine, was the first, publicly, to throw doubt upon corn as the sole etiological factor in the causation of pellagra. In 1905 at the meeting of the British Medical Association, he stated his belief that the disease was caused by a protozoan parasite, transmitted, probably, by a blood-sucking insect. In view of the increase of the disease in various parts of the wold, including America, and because of the obscurity which hangs about its origin, a British commission, with Sambon at its head, has been formed and is now studying the question in those parts of Italy in which the malady is most common. So far as the work of the commission has gone, the theory of Sambon has been greatly strengthened from the epidemiological standpoint, and he has personally communicated to C. H. Lavinder of the United States Public Health and Marine Hospital Service, one of our most earnest investigators into the subject, that he feels confident that he will ultimately be proved correct. Lavinder, writing in *Public Health Reports*, June 3, 1910, sets forth Sambon's theory in detail. These are, in brief, that pellagra is not due to maize because it is found in places in which maize is neither cultivated nor eaten, and is absent from many places in which maize is the staple food. Pellagra is a parasitic disease, because for years the person affected may present some seasonal recurrences, which can be explained only by the action of a parasitic agent with alternating periods of activity and latency, and its symptoms, course, duration, and morbid anatomy, as well as its therapy, are similar to those of parasitic diseases. It is insect borne, because like malaria, sleeping sickness, etc., it is limited to rural places, and more especially to the vicinity of certain water bodies. It has a definite seasonal incidence—spring and autumn, it is not contagious, and neither food not water can account for its peculiar epidemiology. Sambon claims to have detected the particular insect which conveys the disease, which he said is *Simulium reptans*. The chief reasons for this conclusion are it is the only blood-sucking insect which the British field commission has found in its visits to numerous pellagrous districts in Italy. *Simulium reptans*, like *Anopheles maculipennis*, has a world-wide distribution and explains the wide distribution of pellagra. It is found wherever pellagra is found and causes epizootics in animals in America and in Europe, and finally Mesnil has found a protozoan organism in *Simulium*. As Lavinder remarks in commenting on Sambon's theory, the judicial mental attitude of American investigators with regard to the etiology of pellagra is to be commended, for its origin is still an open question. The evidence in support of corn as the causative agent has appeared to be so overwhelming that until this evidence has been clearly controverted it cannot be wholly disregarded. However, the theory of Sambon appears to have strong points in its favor and is worthy of the serious attention of American students. Of course, further and convincing proofs must be forthcoming ere it is accepted. There would seem to be no reason why American investigators should not make researches on the lines indicated by the British Commission for we have the material here in abundance.

Peritoneal Patching of the Aorta.

The advances which have been made during the past few years in the surgery of the blood vessels in the experimental laboratories have been so great and the various steps have followed each other in

such rapid succession, that it is impossible to predict from month to month what the next number of the scientific journals may produce. The transplantation of arteries and veins, and the substitution of one for the other, had hardly become known as a surgical possibility, when Carrel announced that not only could fresh vessels be used for this purpose, but that arteries kept on ice for weeks and months might be used for implantations, and that they would regain their vitality and functionate quite as well as the fresh material. In *The Journal of Experimental Medicine* for March 14, 1910, the same author publishes the results of some experiments perhaps even more startling than those which he has given before in that he has demonstrated that in order to mend a hole in an aorta it is not even necessary to use a blood vessel for the patch. Instead he has taken a piece of the abdominal wall with its attached peritoneum, has smeared it well with vaseline, and has fitted it carefully into the opening made in the aorta, the peritoneum being flush with the interior. The two animals which survived the operation lived and appeared to be healthy. In one case five months and in the other ten months later, the abdomens were opened and the vessels examined. While the blood was flowing it was almost impossible to tell the patch from the original vessel. On excision, however, the location of the patch immediately showed itself in its failure to contract as did the normal vessel. On histological examination it was hardly possible to distinguish between the vessel and the patch, as the peritoneum and abdominal muscle had become so transformed as most closely to resemble normal vessel wall. The chief difference was in the lesser number of elastic tissue fibers in the patch, though these were much more numerous than in the normal abdominal wall muscles. The anatomical transformation of the abdominal wall into aorta was almost complete, and the functional adaptation was perfect. The practical uses of such a discovery are at present impossible to estimate, but they will undoubtedly be great.

The Pathology of Hepatic Cirrhosis.

For many years there has been some difference of opinion as to the nature of the process known as cirrhosis of the liver. On one side have been arrayed the pathologists who believe that the primary process is a perilobular increase of connective tissue, with a secondary degeneration of the parenchyma due to pressure or inanition, while on the other are those who hold that a primary destruction of liver tissue is compensated for by a secondary growth of scar tissue. In recent years the latter view has been held by most pathologists. In the *Deutsche medizinische Wochenschrift* for May 12, 1910, however, Warschauer reports a case which leads him to believe that, in certain cases at least, the older view may be the correct one. The patient died during the early stages of hepatic cirrhosis. The liver was somewhat enlarged and hard, but showed no other macroscopic changes. Under the low power of the microscope the acini were seen to be intact; in the middle of each acinus was the central vein, without pathological changes; the parenchyma cells were arranged in regular radiations; the capillaries were somewhat dilated; around the interlobular vein, for a distance equal to about five times its diameter, were patches of fibrous tissue with small cell infiltration, and grouped around these were liver parenchyma cells between which the capillaries were not visible. On high power magnification, no signs of degeneration could be seen inside the acini. The cells were normally arranged, the nuclei were well stained, and there was no trace of connective tissue growth within the acini. The appearance, on the other hand, of the interacinous periportal connective tissue was greatly altered. Here were found all the signs of active tissue proliferation; small cell infiltration, fibroblasts, young connective tissue cells, and formed fibrous tissue. Such a picture Warschauer maintains, with some reason, could be produced only by a primary interstitial hepatitis.

News of the Week.

Birth and Death Rates in Europe.—Statistics collected recently by Jacques Bertillon show strikingly the decrease in the birth rate in France. Whereas before the Franco-Prussian War the birth rate was in the neighborhood of one million, during the last three years it has been below 800,000. The excess of births over deaths in France last year was 13,500; in Germany, 880,000; in Austria, 553,000; in Great Britain and Italy it was about the same as in Austria, and in Holland the excess was 83,000.

Cholera in Europe.—A dispatch from Odessa states that on June 22 there were 790 cases of cholera under treatment in the city, and that on that day there were 219 deaths from the disease. The Prussian government has detained a Russian immigrant at the immigration station at Ruhleben with symptoms suggesting cholera.

The Board of Inebriety Bill permitting the Board of Estimate of New York City to establish such a board has been signed by Governor Hughes.

The Children's Aid Society in New York City has opened its various summer homes for the season of 1910. The Coney Island Health Home for mothers with sick infants opened on June 27. On the same day the Children's Summer Home at Bath Beach was opened. The new cottage of the Home for Convalescent Children at Chappaqua had its formal opening on July 1, and the boys' camp at Deuville, N. J., received its first installment on July 2. The society is attempting to raise $50,000 for this summer work.

The University of Arkansas.—An agreement has been reached by which the medical department of this university, located at Little Rock, is to become more closely affiliated with the university at Fayetteville. The first two years of the course will be given at Fayetteville and the last two years at Little Rock.

The University of Wisconsin announces a gift of 1,500 volumes on anatomy and the history of medicine from the late Dr. Byron Robinson. Funds for the establishment of a scholarship in anatomy valued at $550 a year are also provided in the bequest. This will be known as the Byron Robinson scholarship in anatomy, and is to be held by both men and women students in medicine. The purpose of this scholarship is to encourage the anatomical, physiological, and pathological study of the sympathethic nervous system.

Honorary Degrees.—At the University commencement exercises held recently a number of medical men received honorary degrees. Yale University conferred the degree of Doctor of Science

upon Dr. Simon Flexner of the Rockefeller Institute for Medical Research. Rutgers College gave the same degree to Dr. Egbert Le Fevre, dean of the New York University Medical College. Bowdoin College gave the degree of Doctor of Science to Dr. Myles Standish of Boston, and Dr. Lucien Howe of Buffalo. The University of Alabama gave the honorary Doctor of Laws to Colonel William C. Gorgas, U. S. A., and Dr. L. L. Hill.

A Rebuke to the Governor of New Jersey.—At a legislative hearing on a medical bill last spring, the Governor of New Jersey lost his temper and applied Rooseveltian terms to two of the physicians present. At the annual meeting of the New Jersey State Medical Society, held this week in Atlantic City, the medical men had their innings and the society unanimously adopted the following preamble and resolution: *Whereas* at the hearing on the medical practice bill the Governor publicly questioned the veracity of the chairman of our committee on legislation and treated representatives of our society discourteously by refusing a proper discussion of the merits of the bill by unceremoniously closing the hearing; therefore, be it *Resolved*, That the Medical Society of New Jersey in annual meeting assembled hereby not only place on record their perfect confidence in Dr. L. M. Halsey but also their deep regret that the Governor of our State so lost control of himself as to reflect discredit upon his high office and dishonor upon the State. And, moreover, the result has been the lowering of the standards of preliminary educational requirements in New Jersey and the consequent loss of reciprocity between our State and New York State.

The People's Hospital of New York had its opening and dedication ceremonies on June 21. The building is fireproof throughout and has accommodations for fifty patients. Most of the equipment was donated, among the donors being the Emperor of Austria, who gave an operating table. The medical board consists of Dr. I. Adler, consulting physician; Dr. C. A. von Ramdohr, consulting obstetrician; Drs. I. M. Rottenberg, A. Fishman, and J. Broder, visiting physicians; Dr. A. Bassler, visiting gastroenterologist; Drs. J. Bieber and M. Landesman, attending physicians; Drs. J. P. Grant, B. Tilton, J. J. McGrath, G. I. Miller, and C. Pfister, visiting surgeons; Drs. S. Strauss, R. Cronson, J. O. Polok, S. Rottenberg, C. Kennedy, and B. Gordon, visiting gynecologists; Drs. K. B. Page and A. Wolborst, visiting genitourinary surgeons; Drs. S. Spiegel, M. Lewson, and S. Forstot, attending surgeons; Dr. M. Davidoff, attending gynecologist; Dr. H. W. Korman, attending genitourinary surgeon; Drs. S. S. Freidman, C. Broder, J. A. Stoloff, J. A. Prager, and M. Rosenberg, assistant attending surgeons; Drs. A. L. Weindrug and L. Polon, assistant attending gynecologists; Drs. G. Wolf, M. Wolper, and J. Barsky, visiting pediatrists; Dr. Z. Sharfice, attending pediatrist; Dr. L. Weiss, visiting dermatologist; Dr. J. S. Price, visiting ophthalmologist; Dr. M. Rosenbaum, assistant attending ophthalmologist; Drs. D. S. Dougherty and I. Grushlaw, visiting laryngootologists; Drs. G. Kremer and I. F. Pasternak, attending laryngootologists; Dr. J. H. Stebbins, Jr., pathologist and curator.

Bellevue Hospital.—The appointments have been announced of two assistant medical superintendents to Bellevue and the Allied Hospitals of New York City. The appointees are Dr. George O'Hanlon of the Riverdale Sanatorium, and Dr. Mark L. Fleming of the detention station at Hoffman's Island.

A Hospital for the Tuberculous Insane is about to be erected in Fulton, Mo., in connection with the State Hospital there. The new institution will be called the Hadley Hospital in honor of Governor Hadley of Missouri.

The Kansas State Board of Medical Registration and Examination has elected Dr. A. S. Rose of Sabetha, *President*, and Dr. H. A. Dykes of Lebanon, *Secretary*.

Medical Club of Philadelphia.—At a reception held June 17, Surgeon-General George H. Torney of the United States Army, and Surgeon-General Charles P. Stokes of the United States Navy, were the guests of honor.

The Alumni Association of the Yale Medical School held its annual meeting June 22, 1910. The election of officers for the ensuing year resulted as follows: *President*, Dr. Charles Craig of the United States Army; *Vice-Presidents*, Dr. S. J. Maher of New Haven, Dr. Seymour L. Spier of New Haven; Dr. H. J. Schlevin of Brooklyn, Dr. A. M. Loomis of Derby, Dr. T. H. Wilson, Jr., of New Haven; *Secretary and Treasurer*, Dr. E. M. Black of New Haven; *Chairman of the Executive Committee*, Dr. C. J. Bartlett of New Haven.

Obituary Notes.—Dr. Jules A. Simon of San Francisco died on June 8, 1910, of heart disease while ascending Mount Vesuvius. Dr. Simon was a graduate of the medical department of the University of California in 1875 and of the University of Paris in 1883. He was at one time president of the San Francisco Board of Health, and for many years held a professorship in the University of California. He was a member of the San Francisco County Medical Society and the Medical Society of the State of California.

Dr. Joseph Chamberlain Caldwell of Buckland, Maine, died suddenly while attending a patient on June 20, 1910, aged 65 years. He was a graduate of the Medical School of Maine in 1870, and a member of the Oxford County Medical Society, the Maine Medical Association, and the American Medical Association.

Dr. Willis B. McMichael of Boston, Mass., died June 11, 1910, at North Edgecomb, Maine, aged 53 years. He was a graduate of the Harvard Medical School in 1881, and was a member of the Suffolk County Medical Society, the Massachusetts Medical Society, and the American Medical Association.

Dr. Emmett C. King of Hartford, Conn., died at his home June 17, 1910, aged 58 years. He was a graduate of the New York Homeopathic Medical College in 1880 and was a member of the Hartford County Medical Club and the Connecticut Homeopathic Medical Society.

Dr. Steven Frost Horton of Peekskill, N. Y., died at his home June 21, 1910, aged 46 years. He was a graduate of the New York University Medical College in 1886, and was a member of the Westchester County Medical Society, and the Medical Society of the State of New York.

Dr. Wm. Erwurzel died at Philadelphia on May 18 at the age of 68 years. He was graduated from Jefferson Medical College in the class of 1868, and a member of the Philadelphia County Medical Society, and the Medical Society of the State of Pennsylvania.

Correspondence.

MORE FEEDING IN TYPHOID FEVER.

To the Editor of the Medical Record:

Sir:—I was much pleased by three articles in the Medical Record last year on "Milk-Free Diet in Typhoid," by Drs. Seibert, Strong, and Kemp. The articles were terse, strong, short, and full of common sense. The line of treatment follows partly along lines that I have practised for eleven years. I have had 240 cases, with four deaths. Two of those that died had walking typhoid and had had profuse hemorrhages before calling medical aid, and neither lived four days after receiving medical attention. The third one came into my care on relapse after being treated for three weeks with "acetanilide." He was sixteen miles away across country, the only way to reach him was by horseback, and naturally he could not receive the best attention. He lived a week in the relapse, but in that time bed sores of large size developed, showing his resisting power to be low. The fourth died the eighteenth day of the disease. He was the last of seven to come down, he having acted as nurse for the others as one after another became ill. The mother was dead and the neighbors refused assistance, so the family fought it out as best they could among themselves, and this young man waited on himself, taking his food and medicine, using the fountain syringe, and bathing himself for fourteen days, when he became delirious and was unable longer to do it. He died the eighteenth day. These four died. Would Brand, or Osler, or Seibert have lost them? Dr. Seibert's success seems to depend on the irrigation of the bowels and the milk-free diet. I have attributed my success to my "typhoid treatment," rectal irrigation, and abundant feeding. It is my belief that typhoid fever may be "gone after" with as much assurance of success as we would go after malaria with quinine, syphilis with mercury, or acute rheumatism with the salicylates. As I say, I have attributed my success more to drug medication than anything else. But have I been wrong? It may be that I have drugged my patients unnecessarily, and the success should be attributed to the rectal irrigation. I have not been a "milk" man by any means, but have insisted on the patient having a variety of food—"anything he can drink." I must say, however, that to get soups properly prepared is a great problem in most homes, and if there is a trained nurse, she is trained, as a rule, to consider anything but milk in typhoid as certain death, and will not, and generally does not know how to prepare a nourishing soup.

There is no therapeutic nihilism in my treatment, nor is there starvation. I have never excluded milk from the diet, but have noticed that those that take least milk and most other foods get along best. (Some day there may be a standard treatment and standard food for this disease.) I give soup by the bowlful instead of the ounce, and cool water (no ice-water) every hour. Each evening a large edema of soapsuds with a teaspoonful of turpentine is given. Hemorrhage is the only contraindication; and in my last one hundred and sixty cases there have been no hemorrhages. There is rarely any tympanites, delirium, diarrhea, or discomfort. The tongue clears, pulse comes down, temperature gradually subsides, appetite returns, skin is moist, no dryness of the mouth, no sordes, nothing typical of typhoid fever after ten days. "What's the matter with Mrs. P.?" I was asked by one of my hospital patients. I answered, "Typhoid." "Well, if that's typhoid fever, I am not afraid of it. She don't look sick." I said, "Come into the ward." I took the party to the ward and pointed out two other patients and said, "Do they look like typhoid?" He said, "Not typical. What are you giving them?" I said, "Plenty to eat and water—and some medicine."

It is the unusually good appearance of the patients that attracts attention, and the short duration of the disease. Almost every case is free from fever in three weeks or less, with few complications. There have been ten pneumonias complicating the typhoid, but none proved fatal. These have not all been mild cases, for the first of the series was in a malignant epidemic, where more than 35 per cent. died under the "expectant" treatment. But they have been of every grade, mild and severe. I feel sure that fully 50 per cent. of the deaths in typhoid fever are due to milk, and 50 per cent. of the remaining deaths due to starvation. It seems curious that even eminent men will not recognize the fact that it takes a considerable amount of "fuel" to keep the human mechanism in working order, even when lying abed. Many a patient has literally starved to death from underfeeding. Compare Dr. Seibert's feeding with the "regulation" feeding of many hospitals and private practitioners ,and one can readily see why Dr. Seibert's patients have such different "term" of fever. Since reading the "Milk-Free Diet" articles last year, I have excluded milk rigidly from the diet of typhoids, and they have all done remarkably well, although I have had only twelve cases.

C. H. Maxwell, M. D.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RESEARCH DEFENSE SOCIETY AT ROYAL COLLEGE OF PHYSICIANS—PARLIAMENTARY GRANT—NURSING DISCONTENTS—OBITUARY.

London, June 10, 1910.

The Earl of Cromer presided at the annual meeting of the Research Defense Society, held on the 4th inst. at the Royal College of Physicians. Sir Douglas Prowell, proposing the report, said it was deplorable that a society should be necessary to defend the good work of research against the machinations of a clique which just now dominated another society (that for prevention of cruelty to animals), which after doing much good work had entered on a wild crusade against science and endeavored to exploit the sentimentalism of people who, though worthy, were not wise. Their readiness to be imposed upon and exploited illustrated the truth and force of Mr. Roosevelt's remark: "Of all broken reeds, sentimentalism is the most broken reed on which righteousness can lean."

Sir David Bruce, seconding, pointed out that there was now no new case of sleeping sickness in Uganda, where, in the past, it carried off 200,000 out of a population of 300,000. That result was entirely due to experimentation on animals. By the same method of research, Malta fever, of which, in 1905, there were 643 cases in the army and about as many in the navy, had been banished.

Thanks were voted to the Earl of Cromer and the Royal College of Physicians for the use of its library to hold the meeting in.

Lord Cromer, responding, paid a tribute to the untiring zeal of Mr. Stephen Paget, and commended also Mr. Keen's book on "Recent Surgical Progress," and summarized that author's reply to the question what the friends of research had done and then what its foes had done? To the latter he said Mr. Keen answered in tones vibrating with justifiable indignation. "Nothing but to stand in the way of progress. Not a single life has been saved by their efforts; not a single household made happy; not a single disease has had its ravages abated or abolished." Lord Cromer passed on to the question whether dogs were to be exempted as proposed by some of the sentimentalists, and claimed that he himself and others loved the dog as much as any. But he knew that about 20,000 stray dogs were put to death in the lethal chamber annually, and the few dogs vivisected suffered no more, and there was no reason for making such exception over other animals, and such legislation could not be justified. Lord Cromer proceeded to ridicule Mr. Coleridge's fanciful proposal that a license to experiment should only be granted to applicants with a certificate signed by at least one justice of the peace and one clergyman that he had a reputation for humanity! Such absurdity was enough, said Lord Cromer, to laugh the bill out of court. But if it had a chance of becoming law he would suggest an amendment: "That no one, even in this free country, should be allowed to speak against vivisection unless he could produce a certificate signed by at least two judges and a brace of bishops that he had a reputation for common sense and accuracy of statement."

In connection with the Parliamentary grant for scientific investigations concerning disease the following special researches have been authorized: 1. Continued investigation into enteric fever, by Drs. Theodore Thomson and Ledingham. 2. Continued research on diphtheria by Drs. Thomson and C. J. Thomas. 3. Continuation of that into flies as carriers of infection, by Drs. Monckton, Copeman, Graham, Smith, Merriman, Nicholl, and Bernstein. 4. Continuation of that on the injurious gases evolved during artificial illumination, by Dr. J. Wade. 5. Preliminary inquiry into relation of certain bacteria to infantile diarrhea, by

Drs. C. J. Lewis, Sheila M. Ross, Thomas Orr, and R. A. O'Brien.

A state of unrest and discontent has prevailed for some time among many nurses. Threats more or less serious have been made by some of the leaders of these ladies, but are looked upon with amusement or contempt, according to the view taken. On Monday evening there was a meeting of nurses employed at St. Bartholomew's Hospital to protest against the appointment of a matron who was not one of themselves, but came from another hospital. Considerable excitement was reported in the nursing world, and letters and telegrams of sympathy were sent to the meeting. It is perhaps natural for any kind of staff to consider promotion from its own members the best way of filling vacancies, and, other things being equal, it is often adopted. Is there not a feeling in medical schools in favor of their own students? But we do not hear of revolts or strikes when an outsider is preferred, as frequently happens. Then it may be said that managers have their responsibilities and their rights as to elections.

But, to return to the malcontents of "old Barts." Many strong statements were put forward, the accuracy of which is not quite evident—a natural incident, says a friend, when women are the speakers. The opener declared the "election of a lady from another hospital set the hands of the clock back." She admitted registration had something to do with it, and it seemed as if the meeting advocated registration such as the medical profession has had. If they knew how little good it has done they would not be enthusiastic about it. A resolution was put forward to the effect that the committee had condemned the efficiency of the educative worth of their medical and nursing staffs, etc., and calling for public inquiry into the management and the nursing home, which was said to be insanitary and a death trap in case of fire. It was not explained how these things had only been just discovered. Mrs. Bedford Fenwick, who is usually present at discussions on nursing, declared in her decided way that the action of the committee was a challenge to the whole nursing profession; that no cooperation, no organization, no protective legislation, no liberty of conscience, no liberty of speech, no degree of self-government should be theirs unless those who claimed them were prepared to pay the price of no professional promotion. This is the sort of assertion Mrs. Fenwick has often indulged in, as she advocates registration. Whether her advocacy will help the malcontents of "old Barts" or terrify the committee remains to be seen.

Of course, the name of Florence Nightingale was heard in this discussion—which reminds me that an "appreciation" of her work lately appeared in the *Medical Press* from one who had seen it in the Crimea. It was written to commemorate her ninetieth birthday and endorsed by another witness of her beneficent work. Many amusing remarks and incidents were made in the article. But it was rather marred by exaggeration—quite as marked as that of the feminine speakers mentioned above. It spoke of the nursing of the hospitals in London and New York as inconceivably bad before Miss Nightingale's work. It said the nurses were generally both drunken and immoral. Now, a doctor who went through a hospital in London as student and eventually became a professor protests against this as a gross libel. He only met with one instance of drunkenness, but he admits there was a good deal of ignorance, though not of the self-assertion which is at present so prominent. So much for London nurses then and now. You can speak for New York.

Mr. James Stantin, senior surgeon to the London Skin Hospital, died on the 3d inst. at the age of fifty-nine. He took the M.R.C.S. in 1876 and contented himself with that single qualification, and that through a period when many seemed to aim at adding as many letters as possible to their names. He devoted himself to dermatology, and became a leading authority. His "Pharmacopœia for Skin Diseases" obtained a good circulation, reaching a fourth edition in 1899. He wrote several treatises on this subject and contributed freely to the Transactions of the Paki and the Wilan Societies and the International Dermatological Congress. He also devised a "skin scraper" and a "toughened gold needle" for electrolysis.

H. R. Greene, Pasha and Lieutenant-Colonel in the Royal Army Medical Corps, died suddenly on the 4th inst. He was educated in Dublin, at Trinity College and the Royal College of Surgeons there, taking its license in 1862, and the following year adding that of the Edinburgh Royal College of Physicians. Entering the army medical service, he was employed in various foreign parts. In Egypt he became First English Director of the Sanitary Administration, and for his valuable services in this capacity was created Pasha by the Kheidive. He retired several years ago, having had the misfortune to become totally deaf.

FORTY-THIRD ANNUAL MEETING OF THE CANADIAN MEDICAL ASSOCIATION.

(From Our Regular Correspondent.)

TORONTO, June 15, 1910.

On June 1, in the Section of Medicine, Dr. George W. Ross of Toronto read a paper on the treatment of acne vulgaris by vaccines. He said that treatment was dependent upon the microorganisms found in the pustules of each case. If the bacillus of acne was alone present, as in many cases of acne punctuata, then the bacillus of acne vaccine was used, but if the staphylococcus albus coexisted, then the albus vaccine was necessary as well. Treatment by vaccines was of great value, but it was important to supplement this specific treatment with careful regulation of the general health. Out of fifty-six cases satisfactory results had been obtained in forty-four cases. In the remaining twelve improvement had occurred in all but four.

On June 2, in the Section of Surgery, Dr. Murray MacLaren of St. John, N. S., read a paper on a case of hemorrhagic cyst of the omentum, which occurred in a negro and which was operated upon successfully. Dr. MacLaren defined a true omental cyst as contained in the cavity of the omentum and not attached to the wall. He further said that such cysts were of rare occurrence. Dr. J. M. Elder of Montreal, however, did not think that these cysts were so common as was generally believed.

Dr. I. Wood of Kingston, Ont., read a paper, in the Section of Surgery on June 2, on appendicitis in children, which gave rise to a considerable amount of discussion and difference of opinion. Dr. Wood presented the statement that appendicitis was more deadly than any other abdominal lesion to persons under fifteen years of age, that it was more prevalent in children, and that the condition was more difficult to diagnose in children than in adults. Dr. Wood gave a history of appendicitis from the time of its earliest mention. In 1867 Parker said that gangrene was more prevalent in children, while Little was the first to make special reference to appendicitis in children. Dr. Wood, who acknowledged that he borrowed his views, to a large extent, from Kelly, argued that appendicitis was in every respect more dangerous in children. It was more sudden in onset, more intense in symptoms, and more deadly in result, and abnormal conditions were more frequently met with in children. From anatomical, pathological, and clinical standpoints appendicitis was more difficult to diagnose in children, and diagnostic features which were clear in adults were obscure in children. That its treatment was more difficult in children was made evident from the fact that the death rate from the disease in children was more than 10 per cent., and in adults between 2 and 3 per cent. Finally Dr. Wood advanced the opinion that the literature of appendicitis in children should be revised. In discussing the matter Dr. Bruce said, in appendicitis occurring in adults or in children operation in the majority of cases should be undertaken at once. Dr. F. Shepherd of Montreal said he did not think that diagnosis of appendicitis in children was more difficult than in adults, but he ventured the remark that surgeons in England were behindhand as regards operating for appendicitis. Dr. A. Primrose of Toronto laid emphasis on the more frequent discovery of appendicitis in abscess form in children than in adults.

On June 2, in the Section of Eye, Ear, Nose, and Throat, there was an interesting discussion on the diseased tonsil. Dr. W. P. Caven read a paper on the effect of the diseased tonsil upon the general system. He pointed out that diseased tonsil was occasionally congenital, and that Hutchinson has suggested that chest affections were often due to enlarged tonsils. Shut your mouth and save your life was a dictum of an old doctor which contained a good deal of truth. At any rate, there could be little difference of opinion with regard to the vast improvement in health frequently brought about by the removal of enlarged tonsils. In tuberculosis the tonsil was an important factor of infection. Those suffering from tuberculosis had often had diseased tonsils. The diseased tonsil removed in time would do away with tuberculous glands. Dr. Caven said that articular rheumatism, too, often fol-

lowed diseased tonsils, and he thought that the diseased tonsil might be the port of entry of the bacteria of rheumatism. He drew attention to the fact that the diseased tonsil had a considerable bearing on other diseases, and among these on appendicitis.

In discussing the surgical treatment of the diseased tonsil there was no agreement as to the mode of operation in the young. Dr. Price Brown of Toronto gave his view, to the effect that up to adult age the tonsil should not be completely removed, for the reason that it has functions in childhood. He pointed out that, while the American surgeons enucleate the tonsil, the German and English surgeons do not, and that the greatest European authorities do not believe in complete removal. On the other side, the contention was made that enucleation of the tonsil at any time of life was the only effectual operation, and that if it were not enucleated adenoids had a tendency to reappear.

In the section of medicine, on June 3, Dr. J. H. Elliott read a paper on the value of tuberculin in pulmonary tuberculosis. He said that experiments had shown beyond doubt that in carefully selected cases it was valuable, but that in critical cases attended with fever it could not be used.

"The Blood in Pulmonary Tuberculosis" was the title of a paper read by Dr. A. F. Miller of Kentville, N. C., in collaboration with L. Brown and J. S. Lupton of Saranac Lake. The contents of the paper were the tabulation of the results of six years' efforts and experiments to ascertain the blood changes and developments in cases of tuberculosis. The results were for the most part negative.

On June 3, in the Section of Pathology, Dr. J. L. Todd of Montreal read a paper on the blood in sleeping sickness. He pointed out that auto-agglutination of the blood was very common in this disease, and, although it was not always seen in infected blood, it was so frequently seen as to lead to the suspicion that there was a connection between this condition of the blood and sleeping sickness. Auto-agglutination was not present at any particular stage of the disease, and might be associated with other diseases, and there did not seem to be any intimate connection between it and sleeping sickness, but, as said before, its more or less constant presence in the disease was more than a coincidence. Professor I. G. Brodie of Toronto gave an interesting address and demonstration by means of carefully designed apparatus of the action of the glomeruli of the kidney. He showed that the action was a true secretory process, and was neither passive nor filtrative.

Among other noteworthy papers read was one by Dr. Amzot of Toronto, provincial analyst, on rabies. He mentioned that Professor McKenzie of the pathological department of the Toronto University had many years ago discovered the same protozoan bodies which were afterward discovered by Negri, and by many supposed to be the cause of the disease.

A considerable amount of business was done by the Executive Council of the association. Dr. John Stewart of Halifax submitted to the executive committee of the council an exhaustive report dealing with the inspection of public schools and school children of Canada. The report made these recommendations: That the boards of education, the Minister of Education, or Council of Education, should appoint a public inspector, and that each province should have an expert medical adviser, who should organize a complete system of medical inspection for the supervision of schools and school children. That the system adopted in British Columbia recently to provide for the medical inspection of schools and school children should be approved by the Medical Association. The following special committee was appointed to consider the question: Dr. Stewart, chairman; Dr. Helen MacMurchy of Toronto, secretary; Dr. Jasper Halpenny of Winnipeg; Professor A. McPhedran of Toronto; Dr. C. J. Fagin of Victoria, B. C., and Dr. J. D. Lafferty of Calgary.

At the last business meeting of the association for this year a resolution was passed asking the Dominion Government to establish a laboratory for the production of antitoxin and other serum for distribution throughout Canada at cost price. It was pointed out that the use of antitoxin in diphtheria had reduced the mortality from 35 to 10 per cent. of the cases.

It has been decided to hold the next annual meeting in Montreal, and the following officers for the coming year have been elected: *President*, Dr. George E. Armstrong of Montreal; *General Secretary*, Dr E. W. Archibald of Montreal; *Treasurer*, H. B. Small of Ottawa; *Finance Committee*, Dr. James Bell of Montreal; Dr. J. L. Fotheringham of Toronto; Dr. Murray Maclaren of St. John, N. B.; Dr. S. J. Tunstall of Vancouver, B. C.; Dr. F. N. G. Starr of Toronto; Dr. F. J. Blanchward of Winnipeg, and Dr F. B. Finley of Montreal.

The social aspect of the meeting was not neglected. There were golf matches and bowling games, and, of course, "at homes" and other entertainments for the ladies. On the afternoon of June 2 the members of the association and ladies went to Niagara Falls as the guests of the Toronto members, and on the afternoon of June 3 the members of the association and ladies went to Guelph as the guests of the profession of that city and of the president and staff of the Agricultural College there.

A large exhibit of medical appliances and drugs was held in the foyer of the Convocation Hall.

The meeting of the association was a great success from every point of view. The attendance was large, the papers read were of a wide medical and scientific range, and, on the whole, of a high standard. As a place of meeting Toronto could hardly be improved on, and it may be said that everything went without a hitch, and that probably the meeting of 1910 was the most successful in the annals of the Canadian Medical Association.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 16, 1910.

Cardiac Syphilis.—The paper of G. G. Sears refers to the varying views on this question and studies recent literature. He says that as there is no pathological lesion apart from the gumma which permits positive diagnosis of syphilitic infection of the heart so there are no clinical signs or symptoms which are pathognomonic of it or essentially different from those which result from other causes. If a single gumma be of small size or a fibrous patch be located in the thick muscle of a ventricle there are no symptoms during any stage of its evolution while a similar lesion in a papillary muscle or in the bundle of His might cause great disturbance. Yet in spite of this fact the author thinks that a probable clinical diagnosis can often be made and sometimes a positive one. The cardiac disturbances during the acute stage of the disease may appear under two forms, one toxic and similar to those which occur in typhoid, pneumonia, and other infectious diseases and the other a true organic lesion produced by interstitial foci in the muscle. Most of these cases whatever their form clear up under treatment and the connection is obvious in making a diagnosis. The following complex is the most important; paroxysmal attacks of cardiac asthma or anginal pain, unequal and irregular heart contractions with muffled heart sounds, an indistinct pulse wave and occasional cardiac murmurs if the aortic orifice be involved in the pathological process, and finally in some cases signs of increasing and persistent heart failure with hypertrophy and dilatation. When these occur in young or middle-aged persons without general arterial sclerosis and without the presence of any definite cause and especially when there is reason to believe that syphilis was acquired ten years or so previously, the diagnosis of cardiac syphilis cannot be doubted. The symptoms generally develop insidiously. A notable percentage of cases die suddenly without manifestations of previous ill-health while numerous cases are conscious of little or no cardiac disturbance until a period of overwork or possibly some special effort leads to an unsetting of the cardiac balance with a rapid development of even an immediate onset of urgent symptoms. The prognosis depends on the stage of the disease and the extent of process. The amount of permanent damage will depend to the extent to which muscular tissue has been replaced and on the location of the fibrous patches. All such patients should undergo the Wassermann test and if the result is positive the treatment is at once suggested. The amount of iodide necessary varies greatly according to the case and the patient's reaction. Mercury is given preferably by injection. Cardiac insufficiency if present should be combated by rest and the medication appropriate to each individual case.

Tuberculous Peritonitis.—A. K. Stone makes a plea for the treatment of tuberculous peritonitis by hygienic rather than by surgical measures. He says that in true cases of the disease in which no other focus can be demonstrated the chances of ultimate arrest under properly conducted hygienic treatment are good. They are not enhanced by surgical intervention without distinct purpose and any such operation must be treated not as itself curative but as a step or incident of the cure. In the absence of a symptomatic demand surgical intervention is not justified. Many patients recover under good simple food, fresh air, and good nursing. Many wounds made in the course of surgery in such cases become infected with tuberculous material and as it takes time for this infection to

develop and make itself felt, patients are often discharged from the hospital with apparently good scars only to be found a few weeks later with a discharging tuberculous ulceration of the scar. These ulcerations are notoriously slow in healing and even years may pass before they close. The weeping of the wound as it is called is often advantageous as it gives ocular proof to the patients that they are not yet well. If, however, there is a primary infection of the lymph nodes behind the peritoneum of the cecum or in the retroperitoneal nodes about the spinal column or in the tubes or gut itself, tuberculous material may invade the peritoneum and be distributed throughout its cavity. When there are definite local symptoms which simulate appendicitis or salpingitis there is no question but that an operation is indicated to clear up any doubt and if a diseased focus or organ is found it should be removed.

New York Medical Journal, June 18, 1910.

Malnutrition in Infancy and Its Relation to Gastric Digestion.—L. J. Tint and L. Breskman refer to the functional activity of the stomach in children under one year of age, both with and without gastrointestinal disturbance. Analyses of gastric contents are given both with and without green stools and vomiting. General conclusions are given as follows: (1) The examination of the gastric contents of eleven children, mostly under one year of age, without vomiting, or green stools, showed a constant presence of free hydrochloric acid, rennin, and pepsin. (2) Examination of the gastric contents of twenty children under one year of age, with green stools, vomiting, and gradual loss of weight, showed an absence of free hydrochloric acid, rennin, and pepsin. (3) That in well developed cases of malnutrition, such an absence of gastric activity was constant and persisted throughout the course of the affection. Considering the data given in the tables, they deem the following worthy of further study: (1) That the stomach very early in life plays an important rôle in digestion through its peptic and rennin activities. Free hydrochloric acid is normally present. (2) That with the onset of green stools is artificially fed and in breast fed children, there is an absence of free hydrochloric acid. 3. That the absence of gastric activity is relatively constant in children suffering from malnutrition. (4) Lastly, that the milk should be carefully examined for the fat percentage, when such is taken into consideration in making up feedings, particularly in asylums for children.

Delayed Menopause.—A. E. Callant speaks of the dangers and therapeutic indications of delayed menopause and presents a table showing the approximate age when the menopause should be established. This table says that when the menses begin at the tenth year they should cease between the fiftieth and fifty-second year; at the other end of the scale, when they do not begin till the twentieth year they should cease between the thirtieth and thirty-second year. The author submits the following general propositions: (1) The menopause in women with healthy reproductive organs should be established abruptly at an age depending upon the age when menstruation first began—early if begun late, late if begun early. This age can be approximately determined, and used as a guide in estimating when the menopause may be expected to occur. (2) The menopause is delayed whenever menstruation continues after the approximate age and is always found to be associated with flexion, version, fixation, neoplasm, tubal disease, syphilis, etc. (3) In delayed menstruation the greatest pathological danger lies in the presence or promotion of the growth of fibroid or malignant tumors. The contributory dangers are due to delay: 1. The patient failing to consult a physician; refuses examination; or refuses operation. 2. The physician delays examination; fails to diagnosticate the condition; fails to recognize the importance of early operation; deludes himself and the patient in the belief that the flow will cease, the fibroid atrophy and time will work miracles; forgetting that the grave alone can silence, cover, and conceal these victims of his delay. (4) The danger signals in delayed menopause are: 1. A typical menstruation; 2, hemorrhage; 3, malodorous discharge; and, 4, pain, which if disregarded lead to disaster and death. (5) At the approximate age the woman has reached the limit of fecundity, therefore the prophylactic removal of a useless, probably dangerous, tumor breeding organ is justifiable, and the one sure method of putting an end to all the dangers. (6) The large number of incurable cases of carcinoma uteri, degenerated fibroids, malignant ovarian and broad ligament cystoma, even in early life, warn us to instruct mothers to teach their daughters the dangers of delay whenever they suffer from dysmenorrhea, menorrhagia, metrorrhagia, leucorrhea, abdominal tumors, etc., especially after they have passed the approximate age.

The Clinical Significance of Silent Fluids in the Thoracic Cavity.—The descriptive term used by F. A. Jones refers to large quantities of transudates and exudates into the thoracic cavity without symptoms. These fluids may be serous, serofibrinous, purulent, or hemorrhagic. In tuberculous peritonitis with effusion where the process has not been active in the lungs he has found in most instances a bilateral effusion with a physical examination of the chest. In these cases there were no circulatory or respiratory symptoms. There was no dyspnea, cyanosis, cough, bulging of intercostal spaces, nor fixation of chest walls. During the past year the author has observed six cases of bilateral hydrothorax complicating acute nephritis, in which there were no circulatory or respiratory symptoms or evidences of dropsy elsewhere. Similar cases have been seen in children convalescing from scarlet fever and pneumonia. Quite often the physical signs are a composite picture of consolidated lung and effusion; particularly, in children where Bacellis's sign obtains, tubular breathing on auscultation. The dead flat note, however, over effusions of whatever nature, can, in the hands of the experienced, be distinguished from the living, resilient, flat note which we sometimes elicit in thickened pleura and in consolidated lung. In the latter, the sounding board vibrates. In the former, it is cracked. In pleuritic effusions, the flat note is dead. In thickened pleura with consolidated lung, it is very much alive. Carelessness in the application and interpretation of physical signs often leads us into diagnostic errors. The author desires to impress upon young practitioners, who possibly have not had quite sufficient hospital training, to be careful how they inspect, how they palpate, how they percuss, and how they auscultate. He wishes to enter his protest emphatically against a number of our recent textbooks using the terms "flatness and dullness" interchangeably.

Journal of the American Medical Association, June 18, 1910.

Enucleation in Panophthalmitis.—R. L. Randolph, while admitting that meningitis is a rare sequel of enucleation in the active stage of a purulent panophthalmitis, thinks that such cases should be watched with care as fatal meningeal complications have followed, especially in purulent panophthalmitis with great phlegmon of the orbital tissues. He reports a series of experiments made to determine whether meningitis could be produced in some of the lower animals by first producing a purulent ophthalmitis and then removing the eye in the active stage of the disease. Rabbits and guinea-pigs were employed and the experiments were always made under etherization. The results of 43 such experiments agree with clinical experience in the human subject, namely, that a death from meningitis thus induced is an exceptional event. It is his practice, however, to abstain from enucleation in spite of the evidence of its comparative freedom from risk. He always makes 2 incisions in panophthalmitic eyes, one on each side of the cornea about a quarter of an inch from the limbus and a little below and parallel to the equator of the eyeball, as he is of the opinion that these incisions constitute a measure safer than enucleation, performing enucleation only when a speedy and painless recovery is very important, as, for example, in old and feeble patients.

Autolysis of Pneumococci.—E. C. Rosenow has investigated the autolysis of pneumococci and offers the following preliminary statement. It seems possible to separate the toxic from the nontoxic or antigenic parts of the pneumococcus by autolysis with sodium chlorid, the toxic portion going into solution. It is impossible to immunize animals with this substance to any marked degree. The injection of the nontoxic portion, on the other hand, causes a marked increase in the immunity curve measured by the specific increase of the pneumococcic opsonin. The use of this substance in pneumonia seems to indicate that it will be a valuable aid in the treatment of this disease though further tests will be still required.

Retroperitoneal Enlargements.—W. H. Allport discusses the diagnosis of retroperitoneal growths, giving illustrative cases of how their progress may be limited. Educated methodical diagnosis is essential, the genius for surgical diagnosis consisting almost always in systematized knowledge. The surgeon should take no man's word, but do his own guessing and do it scientifically, recollecting always that his insight, like all applied knowledge, has its limitations, and acknowledging them in time instead of having them demonstrated later on. Abdominal regions, as usually demarcated, are for the student of anatomy; the surgeon and pathologist are concerned with boundaries. Displaced organs still move most readily toward their normal position and the growth of the abnormally enlarging organs is apt to occur within the normal zone and

fascial plane, usually along, rather than across, the normal cleavage planes. To the surgical pathologist the profitable anatomical study is that concerning the distribution of fascias. Neoplasms are usually closely associated with organs; the irregular and atypical enlargements which follow fascias are apt to be either secondary deposits or chronic suppurations, more likely the latter. When in doubt, one should never forget that arch deceiver, the cold abscess. Chronic suppuration is rarely recognized by the direct method; diagnosis by exclusion is the rule. Attention is especially called to the history sheet, the temperature chart, the blood count and the urinalysis reports as aids for diagnosis. Inflation of the colon by Ziemssen's method often enables one to assist diagnosis by crowding the tumor into one or the other space in front of or behind the posterior layer of the peritoneum. If the growth is thus found to be retroperitoneal, the kidney should be studied again by palpation, urine analysis, the *x*-ray; and, finally, by metallic ureteral catheterism combined with skiagraphy. A number of instructive cases illustrating these puzzling points for diagnosis are given in brief detail, and, in conclusion, Allport emphasizes the puzzling clinical problem afforded by hysteria and functional pain. He says that it is a grave question whether pain which the surgeon believes to be genuine, but which exists alone without other symptoms, justifies him in cutting into the peritoneum or retroperitoneal space. His own observation of such cases has not been favorable to operation. The neglect to recognize and properly appraise hysteria is as frequently the cause of failure of diagnosis as is the failure to identify the cold abscess.

The Therapy of Work.—Man is mentally, morally, and physically so attuned that when disordered his perfect restoration demands intelligent readjustment of each element, says R. S. Carroll. The derangements of the mechanical workings of the body have been subject to increasing surgical skill until we invade every precinct of the body. But this has had its evils, and until recently practically normal organs were sometimes removed and exploratory incisions were made for their "mental effect." The modern physician with his immense therapeutic armamentarium, must still feel the stigma of empiricism as he faces many of the diseases of internal medicine, and one reason is that he has ignored that principle of life connected with, dominating and making the real body, the psyche. The neurologist has been pleading that a certain percentage of invalids are psychically ill. Emotional shock is interpreted through the physical sensations, the individual becomes self-centered, the physician who has a powder for every pain fails to apply his psychology and the patient after passing through the hands of the physician, the oculist, the abdominal surgeon, and the osteopath finally finds cure in the negations of Eddyism, and medicine is rightfully discredited. The neuropath may also be of the hereditary type, and then the case is difficult. The acquired form may result from exhaustion, intoxication, or have its origin in the owner's brain. Nerve integrity is reduced by profitless introspection, morbid self-consciousness, ultrasensitiveness, self-depreciation, cynicism, pessimism, doubt, and, most baneful of all, fear in its many forms. The call is for men practised in the arts of medicine, who, in addition, are students of the human mind. The length of the list of false psychotherapeutic cults but emphasizes the need for true, rational psychotherapy. These cults all assert in a chorus most emphatic that beliefs, though false, may displace morbid ideas and effect cures. Years devoted to the development of a workable, practical psychotherapy have convinced Carroll of the preponderating value of work as a present help and a lasting benefit in the treatment of the nervous. The value of Mitchell's rest cure is unquestioned, but often proves inappropriate or inadequate; but work truly is life. As Hall has said, the human body is made for action. Therapeutically, the proper form of work should be prescribed, well within the strength of the patient and requiring sufficient mental activity to distract attention from the purely physical. Even drudgery has its place. There is a wholesome discipline in work. The mental relaxation and rejuvenation which follow substitution of reasonable physical employment for high-pressure mental strain cannot be gainsaid. Wholesome benefits come to the mind from the physical exaltation following the normal use of our muscles. The greatest influence of work as a therapeutic measure rests in the mastering of self which comes with work, and when self-mastery replaces indulgence and doubt of one's strength is replaced by faith, when morbid self-centeredness, that miserable dwarfer of the soul, gives way to an externalizing self, then the passion for material comfort will lose its devitalizing power, and a mastery will ensue superior to petty discomforts of temperature and weather, the habits of our neighbors' children and the din of traffic, a mastery superior to the miserable hyperesthesias and dysthesias so incident to nervousness. Such will ever be the mission of work when divorced from damaging moods.

The Lancet, June 11, 1910.

Imperforate Hymen in Sisters.—Two cases of this nature are reported by W. B. Mayne. The first was a girl of 19 years. Her mother had noticed that for some time she had walked in a peculiar manner and that she had never menstruated. The patient had suffered for some months with abdominal pain and had recently had a swelling of the genitals. Examination revealed a hematocolpos, the uterus being enlarged to the extent of a four months pregnancy and protruding between the labia there was a convex bluish swelling of the size of half a billiard ball. The vaginal septum was incised and there drained away a large amount of a viscid almost meconium-like fluid which was not measured. One week later, the incision showing a tendency to contract, the girl was anesthetized and the fibrous septum was wholly broken down; the os uteri was found to be still markedly patulous and edematous. The sister, a girl of 16 years, who had never menstruated, was found to have a wholly imperforate hymen which was incised and freely stretched but there was no retained fluid.

Fatal Case of Gastric Tetany.—G. A. Gordon was called to see a woman who had a fit. On arrival he found the woman, 48 years of age, perfectly conscious. She had had many years a severe indigestion, vomiting nearly everything she ate. Examination showed the arms flexed at the elbows and wrists, the arms being folded over the chest. The fingers were bent at the metacarpophalangeal joints and extended at the terminal ones. The legs were perfectly rigid and the toes flexed. It required considerable force to straighten the arms or to flex the legs. The stomach was greatly dilated and the presence of a small mass in the region of the pylorus was suspected. The abdominal muscles were fairly rigid. Potassium bromide and chloral failed to relieve the condition. One hour later the patient was becoming delirious and cyanotic. Chloroform relaxed the limbs only slightly. In a short time the patient became delirious again and died in about four hours after being first seen. The author believes that had she been seen earlier she might have been saved.

Rat-Bite Fever.—G. S. Middleton reports the case of a girl of 3 years who had been bitten by a rat on the back of the left hand. The wound had already healed, but two weeks later the hand and arm had begun to swell and had become red and painful and a lump had appeared in the axilla. She was transferred to hospital and had quite a high fever which recurred in short attacks in the course of the next month. These attacks were not accompanied by any swelling of the arm. During the third febrile attack a red measly rash on the cheeks, forehead, and legs appeared but none on the trunk. A rash of similar character came on during each of the following febrile attacks. No cause for this peculiar fever could be assigned. It often rose to 104° or 105°. Recovery ensued, there being no surgical intervention. Examination of the blood during the earlier stages revealed a slight leucocytosis, many of the cells containing an undue amount of small black granules. In fresh specimens the red cells contained one or more rod-shaped bodies which showed a certain amount of movement, but these were not visible in stained specimens and their nature was not determined. In one fresh film there was discovered a diplococcus which seemed to have a capsule. Cultures from the blood made in several different media gave a growth in only one tube—namely, in anaërobic gelatine. This growth had a reddish color and under the microscope showed a diplococcus without a capsule. The organism was an unfamiliar one, and its pathogenic properties were not investigated.

Papilloma Causing Hydronephrosis in a Horse-Shoe Kidney.—The patient of J. Morley was a man of 32 years with the usual symptoms of the condition stated in the title of the paper. A diagnosis of renal growth, probably sarcoma, was made and nephrectomy determined on. Incision was made and a fluctuating tumor found. An attempt to draw it out through the wound led to the tearing of a hole in the cortex. Examination was unable to determine the presence of a kidney on the opposite side. The renal structure on the operated side had every appearance of a horseshoe kidney. The author follows out the technical description of the operation. On the second day thereafter the patient began to have violent and distressing hiccough. On the fifth day the pulse began to fail and the urine to grow scanty, and on the next morning the patient died. Examination of the cystic growth removed

showed on its ureteric aspect a sessile papillomatous growth fungating into the cyst. It was remarkably like a papillomatous ovarian cyst in appearance. The growth completely filled the pelvis of the kidney and it was with difficulty that a probe could be passed up from the ureter through it. The combination of a papilloma with a horseshoe kidney has not, to the author's knowledge, been previously reported. In such a case he thinks that the evidence of cystoscopy and radioscopy would be of doubtful value.

British Medical Journal, June 11, 1910.

Carcinoma of the Rectum Appearing Simultaneously in Husband and Wife.—C. H. Whiteford reports three cases. On the husband's side there was nothing of importance in the history. On the wife's side seven relatives died from malignant disease. The patients have been married thirty-four years. In the case of the husband, a very stout man, aged 63, the first symptoms—evacuations many times a day of small amounts of liquid feces, with small quantities of blood—commenced in April, 1909. Six months later (October, 1909) he was examined and an inoperable growth high up in the rectum was found. On November 9 left inguinal colostomy was performed. All the tissues were very fatty and friable. The mesentery only just permitted the bowel to be fixed outside the abdomen. At the present time (April, 1910), five months after the colostomy and one year from the onset of symptoms, the patient appears to have taken a new lease of life. A daily morning enema empties the bowel, from which neither feces nor flatus escape during the rest of the twenty-four hours. There is no pain, discharge of blood from the rectum has almost ceased, and the patient feels so well that he is actively carrying on his work, which involves much standing and talking. In the case of the wife, a thin, delicate multipara, aged 60, the symptoms, similar to those of the husband, commenced in May, 1909. Ten months later, March, 1910 (some one having suggested that the disease was uterine), the patient was examined and nothing uterine was found, but in the rectum a large growth blocking the lumen 3 in. from the anus. Left inguinal colostomy was performed, fixing the portion of bowel immediately below the splenic flexure. Seen two months after operation the patient is much less weak and the rectal discharge is very little. The high colostomy appears to have prevented prolapse, while the new opening functions as well as that of the husband.

Trigeminal Neuralgia and Its Treatment by Alcohol Injection.—W. Harris says that the alcohol injection treatment is indicated in the following conditions in any persistent neuralgia. (1) When the site of irritation or injury to the nerve is more or less peripheral so that the nerve can be injected on the central side of the lesion. No benefit results from alcoholic injection of a nerve below the point of lesion. This method is therefore contraindicated in tabetic and postherpetic neuralgia. (2) When paralysis of the affected nerve will not cause extensive muscular palsy. Thus injections into the sciatic nerve or into either of the nerve trunks of the upper extremity is contraindicated. The dangers to be guarded against are: (1) In injecting to the foramen rotundum, never inject at a greater depth than 5 cm. for an average-sized skull, or, a better guide, be careful not to sink the needle more than 7 mm. past the anterior edge of the external pterygoid plate. This precaution will prevent the optic nerve being injured. If the injection be made too horizontally, it will pass beneath the superior maxillary nerve and reach the sphenopalatine foramen, and will be felt in the nose. If directed too high, the sphenoidal fissure may be reached and the branches of the third nerve may be damaged, causing diplopia and dilatation of the pupil. (2) In making the injection for the foramen ovale, for the third division of the fifth nerve, if the needle is directed too low and too deeply, more than 4¾ cm., the pharynx wall or the Eustachian tube may be punctured; if too far back, the middle meningeal artery may be injured, and it is conceivable that if directed much too far back by a person with no experience even the internal carotid artery or jugular vein might be injured. Of the author's thirty-three cases treated by this method, thirty-one were completely relieved of all pain; of these nine received the injection under chloroform although in seven the author had previously attempted to make the injection under ethyl chloride spray. In seven of the nine the injection was made through the foramen ovale and in five the foramen rotundum.

Mechanical Effects of a Massive Right-sided Pleural Effusion.—Autopsy notes in one case are given by A. C. Ceddes. They must be read in the original paper as they cannot be well abstracted here. The arteries of the subject were injected under a low pressure with a corrosive-carbolic glycerine preservative, the venæ cavæ and their tributaries to the first valves with 15 per cent. formalin. This method of preservation secures that the majority of the tissues retain an almost lifelike consistency, whereas the heart, liver, and kidneys are firmly, and the lungs partially, fixed. In connection with the displacement of the thoracic viscera the most striking fact in the case reported was that the inferior vena cava and the pericardial attachment of the diaphragm had moored the mediastinal structures as efficiently inferiorly to and through the diaphragm as the great vessels, trachea and esophagus, moor them superiorly to the margins of the thoracic inlet.

Berliner klinische Wochenschrift, May 30, 1910.

Absorption of Radium Emanations Through the Skin.—W. Engelmann discusses the use of radium emanations by means of baths, packs, and local applications. He carried out some experiments to show that the effectiveness of such methods was the result of direct skin absorption. Healthy persons were given emanation baths, so arranged that the head was entirely outside of the bath. The expired air was tested for radioactivity before, during and after the baths. The emanations were found in the breath in every case, their amount being proportional to the length of exposure in the baths.

Münchener medizinische Wochenschrift, May 24 and 31, 1910.

The Treatment of Erysipelas by Hot Air.—Carl Ritter discusses the Bier hyperemia method of treating infections, and, especially, erysipelas. He believes that the usual method of trying to prevent absorption of toxins in such a condition is wrong, and that such absorption should be encouraged instead of hindered. He has applied the principle to erysipelas by treating it with hot air, and he reports fourteen cases with excellent results. In acute early cases the temperature fell rapidly by crisis; in the older cases by lysis. Usually the spread of the disease stopped at once; but occasionally it continued for one or two days and then subsided.

The Etiology of Lupus Vulgaris.—Max Kruger has investigated the tissues of cases of lupus for the presence of the tubercle bacillus. He found the organisms in practically every case examined, was able to grow them in culture media, and to inoculate animals. The organisms were found by the antiform method. The organism was found at times in the form of the rods by the Ziehl's stain, but were frequently as Much's forms.

Hyperemia as After-Treatment of Extirpation of Tuberculous Glands in the Neck.—Heinrich Mohr recommends using Bier's passive hyperemia following operations for cervical adenitis of tuberculous origin. He says that it is generally accepted that the absorption of edema and exudates is delayed by passive hyperemia and hastened by active hyperemia. However, according to researches by Klapp, the final result of the hyperemia is an increase of absorptive activity following an initial delay lasting as long as the bandage is in place. The hyperemia treatment following extirpation of glands appears to aid in destroying any tissue which may remain behind and thus prevent recurrences.

Deutsche medizinische Wochenschrift, May 19 and 26 and June 2, 1910.

Brain Puncture.—Kurt. Pollack describes a method of making exploratory puncture of the brain substance, which he says is of value in the diagnosis of acquired hydrocephalus, circumscribed fluid in the meninges, as cysts and exudates, brain cysts, dural hematomata, and brain abscess. In hydrocephalus, circumscribed meningeal exudates, uncomplicated cysts, and dural hematoma, the puncture is, in certain cases, of distinct therapeutic value.

Hemoglobinuria Nephritis in Pneumonia.—Wilh. Doevenspeck reports three cases of acute lobar pneumonia, in which at the height of the disease there was a marked hemoglobinuria, with hemoglobin stained casts. As to the cause of this condition, the author thinks that the favorable results in all the cases preclude the possibility of the hemoglobinuria being the result of hemolysis produced by a pneumococcus septicemia. It appears to him more probable that the condition resulted from exposure to cold. One of the patients was exposed and soaked through in a storm on the way to the hospital. The others had had ice caps on their heads, cold applications to the chest, etc. The author believes that if the urine of every case of pneumonia was carefully examined for hemoglobin it would be found in a considerable proportion of the cases, especially those in which ice applications were used.

Cystic Calculi in Children.—George Berg says that

diagnosis of cystic calculi in children is not difficult if the physician will examine for them. The history rarely gives much indication of the presence of the stones. Lithotripsy in children is difficult, both as to the crushing of the stone and the removal of the fragments, the difficulty being in inverse proportion to the age of the child, and in direct proportion to the size and hardness of the stone. In adherent stones suprapubic cystotomy is the operation of choice. Complete closure of the bladder is always a great risk, and rarely hastens the healing of the wound. The permanent catheter should be allowed to remain as long as necessary, and in every case until the bladder wound is completely closed.

The Specific Treatment of Tuberculosis by the Various Tuberculin Preparations.—Jochmann has investigated the action of the chief forms of tuberculin, the "old tuberculin" consisting of the bacillus-free bouillon in which the organisms have been grown, the bacillus emulsions, and the bovine tuberculin, upon various forms of tuberculosis. He found that the most successful method of treatment was by a combination of the "old tuberculin" and the emulsion. In children the best results were obtained in cases of adenitis. The general condition of the patients improved, the glands disappeared, and the von Pirquet reaction changed from positive to negative. In many cases of bone and joint disease the results were most satisfactory. In pulmonary disease in children over three years of age marked improvement was found, but in infants the treatment appeared to be without results. In adults in the first stage of the disease, treatment lasting over three to four months was followed by excellent results; the râles disappeared, the appearance improved, the subjective symptoms were relieved, and the weight increased. Cases in the second stage also showed improvement after five to six months. Gains in weight as high as twenty pounds were not rare. The amount of sputum and number of bacilli decreased. In the third stage of the disease improvement was the exception. Good results were obtained in cases of lupus and disease of the testicles, bladder, and kidneys. The author recommends treatment first with the "old tuberculin" and then with bacillus emulsions. The length of time that the treatment should be carried out depends upon the time required to reach the maximum dose, the disappearance of the von Pirquet reaction, the formation of antibodies—in fact, upon the sum of the biological and clinical results. If the râles, sputum, and bacilli have disappeared, and the previously positive cutaneous reaction has become negative, the treatment may be stopped. The author, however, advises that after a lapse of three to four months a new von Pirquet test be made, and if this is positive the treatment should be repeated. This may last much shorter than the first treatment, as the patient, as a result of the first course of treatment, is less susceptible to tuberculin than formerly, and the treatment may be pushed.

A Simplification of Abdominal Palpation.—Galambos states that the main difficulty in palpation of the abdominal organs results from spasm of the abdominal wall. He recommends, in order to overcome this, the following procedure. Before palpating the organ the hand which is not to be used for palpation is placed upon the abdomen a short distance from the organ which the examiner wishes to feel. The hand is pressed gently but firmly and deeply into the abdomen and then is moved toward the organ to be palpated, the skin, fat, and muscles thus being moved with it. This being properly done, the other hand is placed on the site of the organ to be examined and palpation is done as usual. By this means the spasm of the muscles is reduced, and the organ may be felt with greater ease.

The Course of Laryngeal Tuberculosis in Consumptives Treated by Artificial Pneumothorax.—A. Da Gradi has examined the condition and course of the laryngeal lesions in a series of cases of consumption treated by artificial pneumothorax. In such cases in which the cough was relieved by the operation a marked improvement was noted in the laryngeal condition. He says that the efforts of laryngologists to treat laryngeal tuberculosis as a local condition have given very poor results. Nothing else could have been expected as long as the cough and expectoration which so markedly influence this local lesion were not stopped. His cases prove that local treatment of the larynx can give good results if this source of irritation is done away with. He was able, contrary to all expectations, to attain results better than he ever had done before with the usual means of treatment, and at times practically without local treatment. In no cases were heroic local measures employed. In one of the worst cases, though practically no local measures were used, the disease was not only stopped, but rapid and marked improvement was seen.

Inoculation of Guinea Pigs with Syphillis.—Hoffmann says that recently successful inoculations of rabbits with the spirochete of syphilis have been made. He has experimented in order to do the same with guinea-pigs. He inoculated the testicles of three guinea pigs with tissue obtained from a syphilitic tumor of the testis of a rabbit. Fourteen days later there was seen an ulcer with a dirty base, thickened borders, and indurated foundation. Five days later the ulcer showed signs of healing but still had marked induration. In the secretions from the ulcer large numbers of the *Treponema pallidum* were found.

The Significance of Mineral Salts in the Pathology and Therapy of Edema.—Ernst Schloss has carried on a series of experiments by administering various salts to infants. He found that each increase of the salts ingested caused one of two actions on the body, either a retention of fluids with edema or a diuresis. This, he says, has a decided importance in the therapy of edema, in that any salt which has no direct diuretic action, is contrindicated in nephritis as it tends to increase the edema of the disease. The important point in deciding on a salt is to see whether or not it produces edema. As to the kind of neutral salt to be given in such cases, the calcium salts are to be recommended in preference to the potassium as their power of extracting water is much greater. If a basic salt is indicated potassium bicarbonate and calcium carbonate are to be preferred to the usual sodium bicarbonate, the last tending more to produce retention of water and edema. He has shown that it is possible with intact kidneys to reduce edema in an infant in whom an "idiopathic" edema was produced by a diet of buttermilk. The administration of small doses of calcium phosphate caused the edema to disappear within two days. In a like manner a rapid increase of weight produced by sodium chloride disappeared with the administration of calcium chloride. The theoretical findings therefore have a practical significance.

Kidney Diabetes.—Siebke reports the case of a man in whom at the height of a chronic nephritis there developed a glycosuria of an unusually constant sugar percentage (0.1-0.2 per cent.) It evidently was not the usual metabolic diabetes as the sugar content of the urine was entirely independent of the food. The cause of the diabetes must have been some functional derangement of the kidneys.

French and Italian Journals.

The Systematic Treatment of Bronchopneumonias of Children by Inhalations of Oxygen.—Weill gives the results obtained during an experience of a year in the treatment of bronchopneumonias with inhalations of pure oxygen. This treatment is not symptomatic solely, but is directed against the specific septic process of the disease, which he considers to be a descending infection communicated from the nasopharynx. The technique is simple, the remedy harmless, and the clinical results excellent. It may also be used as a prophylactic measure in bronchitis of severe type, to ward off bronchopneumonia. The inhalation is given from rubber bags of oxygen with a mask which covers nose and mouth, and they are repeated every hour or half hour, creating a veritable atmosphere of oxygen. The immediate effects are good; the pulse is slowed, temperature and respiration lowered, and dyspnea lessened. As soon as these good effects wear off the inhalation should be repeated. The course of the disease is shortened, and its severity lessened. A large proportion of the cases treated are cured.—*Lyon Médical, January 2,* 1910.

Treatment of Puerperal Infections.—Barsonyi thinks that we have not gained much in our treatment of puerperal infection. He has used for many years a treatment that was at once simple and effective. It is the intravenous injection of corrosive sublimate, in doses of five milligrams, to be repeated as often as is necessary. The value of the dose is noted by its effect on the temperature, which should be lowered promptly. There is no need for local treatment other than vaginal cleansing, and curetting and intrauterine injections are useless and injurious. General supportive measures are in order. The mercury affects saprophytes less rapidly than the other germs; the most rapid action occurs in pure pyemia; between the two are found the septicemias of lymphangitic type. This method is so simple that it can be carried out in any workman's house, without a special nurse, and without removing the patient to the hospital. In the author's experience it has been promptly successful.—*L'Obstetrique, November* 11, 1909.

Book Reviews.

The Anatomy and Physiology of the Female Generative Organs and of Pregnancy. By Arthur E. Giles, M.D., B.Sc. Lond., F.R.C.S. Edin.; Gynecologist to the Prince of Wales' General Hospital, Tottenham, and Surgeon to the Chelsea Hospital for Women. Third Edition. New York: Paul B. Hoeber, 1910.

This little book of twenty-two pages is too elementary to be of any great value except to the student. There are, however, explanatory plates which are of value, and which can be studied with profit.

Medical Diagnosis. A Manual for Students and Practitioners. By Charles Lyman Greene, M.D., St. Paul, Professor of Medicine and Chief of the Department in the College of Medicine, University of Minnesota; Attending Physician, St. Luke's Hospital and the City Hospital; Chief of the Medical Clinic in the University Hospital; Member of the Association of American Physicians; the American Therapeutic Association; the American Medical Association; author of "The Medical Examination for Life Insurance and its Associated Clinical Methods," etc. Third Edition. Revised, with 7 colored plates and 248 illustrations. Philadelphia: P. Blakiston's Son & Co., 1910.

In his preface to the first edition of this manual the author stated that he had tried to make it a concise, practical, and thoroughly modern handbook of convenient size and form. In order to do this he had not contented himself with rehashing standard descriptions of familiar bedside pictures, but had given in an exceptionally clear and concise manner the important usual and unusual features in each case, and he also devoted a proportionally large space to the clinical laboratory. It is in this latter feature that the book especially excels, in having kept pace with the rapid strides of laboratory diagnosis. The present edition was required by this development of laboratory methods and in producing it the author has brought it most thoroughly up to date. The reviewer has had occasion to refer to this book several times for some small point in the technique of a stain or a test and has never failed to find the exact information desired, not only as to what to do, but also what not to do. The book is printed on very thin paper, which enables the 725 pages of useful and valuable information to be held between two flexible covers in such small space that it can be slipped into the pocket.

Practical Handbook of Medical Electricity for Students and Practitioners. By Herbert McIntosh, A.M., M.D., member of the American Medical Association; Fellow of the Massachusetts Medical Society; Fellow of the New England Association of Physical Therapeutics, Member of the American Electro-Therapeutic Association, etc., etc. Boston: Therapeutic Publishing Company, Inc., 1909.

This book is divided into two parts. Part I., which comprises two-thirds of the book, confines itself strictly to the physics and the physiological action of the various electrical currents, radium, and light. It contains just such information as every man who is to use electricity in therapeutics should know, and a great many do not. Batteries, electrodes, static machines, dynamos, converters, and all the other forms of apparatus used in medical electricity are not only described but are explained. Part II. is devoted to therapeutics and it sticks closely to its subject. The subjects are taken up in anatomical order, and each disease in each region which is amenable to electric, light, or radium treatment is given, the form of electricity indicated, and its action stated. The last chapter, entitled "A Summary of Treatment," takes up in alphabetical order all the disease named from acne to xanthoma, states the form of current advised and refers to the proper page in the text. The title of a handbook is well given as the arrangement, classification, and indexing are so excellently done that the book will prove to be very handy to every electrotherapeutic established or in embryo.

Living Anatomy and Pathology. The Diagnosis of Disease in Early Life by the Roentgen Method. By Thomas Morgan Rotch, M.D., Professor of Pediatrics, Harvard University, Philadelphia and London: J. B. Lippincott Company, 1910.

This volume is a wonderful example of the bookmaker's art and of the ability of a publisher to make of a subject which is in itself not large, a book of the proportions of the usual text-book on internal medicine. The first impression upon seeing the book is of wonder how it might be possible to construct such a mammoth work out of the *x*-ray in pediatrics. On opening the book, however, the explanation is soon found in the thickness of the paper, the immense size of the type, and the impressive width of the margins. A closer look shows that the book really consists of but 218 pages of text, which could easily have been put into seventy-five pages, and of 264 *x* ray plates. Aside, however, from the extraordinary exhibition of "padding," the book if called an atlas of the *x*-ray in childhood, may well be considered a remarkable piece of work. The text is in no way exceptional, but the plates and their arrangement certainly are. Starting with the normal child this development is given from intrauterine life to puberty, the various parts of the bony system being shown as they appear at each year of life. Division II. is devoted to the wrist joints, and Dr. Rotch's recent work upon their development as an index of efficiency. Following this are divisions upon diseases of the newborn and nutrition, and then diseases of the thorax and abdomen, foreign bodies, and disease of the extremities. The plates, which were made by Dr. W. George are superb specimens of *x*-ray photography, and the work of the publishers in reproducing them is much to be commended, while the labor of Dr. Ratch in selecting, classifying, and editing has been most successfully accomplished. The book is a valuable addition to the literature on pediatrics as well as on roentgenology.

The Practical Care and Feeding of Children. By Mary A. Duns, Graduate of the Woman's Hospital, Chicago, Ill. Second Edition. Revised and Enlarged. Chicago: Chicago Medical Book Co., 1909.

This little manual is written for young mothers by an obstetric nurse. It contains very full directions for the various duties of nurse and mother to the young child, and goes into useful details in a thoroughly commendable manner. Where the author confines herself to the proper duties of a nurse as in receipts for older children, the giving of the bath, and the suggestion of clothing, she does her work well. The infant feeding tables are all made up for the use of cream and milk instead of top milk. There are a few statements made with which many will disagree, for example, that "it is very unwise to nurse a baby entirely—it is much better to commence at two weeks giving one bottle each day," and again in speaking of lime water, that "cow's milk contains a great deal of acid." Barring, however, a few such exceptions, the book contains plenty of useful information, placed in a concise, if rather didactic form, and if the author's occasional excursion into the realm of the physician be not taken too seriously the booklet is of value.

A Practical Guide to the Administration of Anesthetics. By R. J. Probyn-Williams, M.D., Senior Anesthetist and Instructor in Anesthetics at the London Hospital, Lecturer on Anesthetics at the London Hospital Medical College, Anesthetist at the Royal Dental Hospital of London, Lately President of the Society of Anesthetists. Second Edition. London and New York: Longmans, Green & Co., 1909.

It is very satisfactory to find that the administration of anesthetics has come to be regarded as a most important branch of surgical therapeutics. A proof of this is furnished by the numerous works on anesthetics which have appeared in recent years, and among those which have achieved the distinction of a second edition is that of Dr. Probyn-Williams. This work attempts to supply in as small a form as possible the essential points in the administration of anesthetics and is intended for the practical instruction of medical students. This, the revised second edition, also contains descriptions of methods and apparatus which have come into general use during the last few years. Thus, two new chapters are devoted to ethyl chloride and spinal analgesia, and also a brief description of the so-called delayed chloroform poisoning has been added. The book is very well written and very complete, the chapter on the "choice of the anesthetic" being particularly good. There is also included a chapter on spinal analgesia, a subject which has become very popular (?) owing to the numerous newspaper articles on the same which have appeared. The writer considers, however, that this method is still in the experimental stage, and the class of cases in which it may be employed has not as yet been defined. Williams' book is suitably illustrated with pictures of apparatus in general use in England and its value to American readers would have been very much enhanced if descriptions of some of the well-known American contrivances, such as the Bennett and Gwathmay inhalers, had been included.

Diseases of the Stomach and Intestines. By Robert Coleman Kemp, M.D., Professor of Gastrointestinal Diseases in the New York School of Clinical Medicine; Visiting Gastroenterologist to the New York Red Cross Hospital; Gastrologist to the West Side German Dispensary; Consulting Physician, Gastrointestinal Diseases, to the Manhattan State Hospital; Member American Medical Association. Philadelphia and London: W. B. Saunders Company, 1910.

This book is a large volume of 750 pages, devoted to the practical clinical discussion of the diseases of the stomach and intestines. The purpose of the book appears to be to teach the man who knows nothing about the subject how to take care of patients whose digestive apparatus is out of order. It presupposes no knowledge and takes nothing for granted, entering with painstaking accuracy into all the minor details, such as the methods of lavage and proctoclysis. The chapter on gastric analysis gives well and in detail the better known laboratory methods of diagnosis. Careful diet tables, giving the amount of carbohydrate, fats, and proteins, as well as caloric values are given. Later the various diseases are taken up separately and their diagnosis and treatment described. In diagnosis the author uses comparative tables extensively, thus giving at a glance and in an easily remembered form the essentials which must be learned. The book is painstakingly prepared, and is profusely illustrated with excellent photographs of the human body, with topographical anatomy marked on the skin, and with drawings, most of which are decidedly crude. The diction, while clear, is decidedly choppy, with paragraphing far too profuse. The work of the publisher is well done.

Clinical Examination of the Urine and Urinary Diagnosis. By J. Bergen Ogden, M.D., Medical Chemist to the Metropolitan Life Insurance Company, New York. Third Edition, Revised. Philadelphia and London: W. B. Saunders Company, 1909.

This book is a little more ambitious than most of the works on the subject which are more apt to be in the form of pocket editions, as it is sufficiently large to be classifiable as a text-book. Its increase in size seems, however, to be obtained more by thickness of paper and size of type than by any especially large amount of subject matter, and in the large form it does not seem to have lost conciseness. There are many books upon this subject on the market, all of which show a marked similarity in form and matter. The present edition is possibly a little above the average in the quality of the plates and cuts, which are distinctly good. The book is comprehensive and still not verbose, and can safely be recommended to those needing an accurate clinical guide to uranalysis. An appendix deals briefly with life insurance examinations.

Preparatory and After Treatment in Operative Cases. By Hermann A. Haubold, M. D., Clinical Professor in Surgery and Demonstrator of Operative Surgery, New York University and Bellevue Hospital Medical College, New York; Visiting Surgeon Harlem and New York Red Cross Hospitals, New York, etc. New York and London: D. Appleton & Co., 1910.

There are several features of interest connected with this book which constitutes one of the latest additions to the numerous works of this character which have been issued in recent years. Dr. Haubold's book seems to be directed primarily to the general practitioner (an unfortunate term), and seeks to prepare him as an associate and helper of the surgeon. The writer is particularly impressed by the idea that in all but exceptional cases the preparatory and after-treatment in surgical operations should be left to the practitioner whose patient the subject happens to be. There are obvious reasons, however, why an arrangement of this kind would in many instances be unsatisfactory both to the family physician and the patient on the one hand and the operator on the other. In those cases, however, where such an arrangement can be applied, Dr. Haubold's book will serve as an excellent guide. The book is intended to give all the necessary information as regards to the handling of a case about to be operated upon from the time the operation is decided on to the making of the incision, and then takes up the case again from time the operative technic is ended until the recovery is complete. The book under discussion is the most extensive of its kind which has thus far been published, including about 650 pages with over 400 illustrations. If the contents were limited, however, to the strict interpretation which the title of the book conveys, the necessary material could be included in a considerably less number of pages. The thirty-four chapters which make up the book comprise not only a description of the preparatory and after-treatment of the patient, but also considerable material of distinctly surgical interest, such as the treatment of wounds, sutures, and ligatures, and the sterilization of instruments. The after-treatment is very completely described in a series of chapters which take up the surgery of the various regions of the body. In conclusion there is also a very complete index. The book may be described as thorough and complete and will undoubtedly prove most satisfactory to those for whom it is intended. One of the features which adds to its general interest is that not only are the various steps necessary to the preparation and after-treatment of an operation described, but the reasons for these various procedures are briefly explained.

Kompendium der Rontgen-Therapie. By Dr. H. E. Schmidt. Second Edition, with 36 illustrations. Berlin: August Hirschwald, 1909.

This little work aims to present to the student and practitioner a concise exposition of the theoretical and practical aspects of roentgen-ray science. In the five years which have elapsed since the appearance of the first edition, the advances which have been made in this subject relate mostly to the dosage of the medium and its extension in certain directions and restrictions in others. These changes are taken note of in the present edition without overstepping the original bounds as regards the size of the book. The author is well-known as a frequent contributor to the literature on the subject of *x*-ray therapeutics, and has succeeded in producing a most valuable and complete work in a small compass. It is unfortunate that the book lacks an alphabetical index—a not uncommon fault in German publications.

Theoretical Principles of the Methods of Analytical Chemistry Based Upon Chemical Reactions. By M. G. Chesneau, Ingénieur en Chef des Mines; Professeur d'analyse minérale a l'école nationale des Mines. Authorized Translation by Azariah Thomas Lincoln, Ph.D., Assistant Professor of Chemistry, Rensselaer Polytechnic Institute; and David Hobart Carnahan, Ph.D., Associate Professor of Romance Languages, University of Illinois. New York: The Macmillan Company, 1910.

We shall probably best serve the interests of our readers by giving an idea of the contents of this volume. In the first chapter, the author examines the influence of the physical state of the precipitates (size of grains, crystalline state, colloidal state) upon their purification by washing. In the next chapter he studies the theoretical principles involved in the methods of analysis based upon irreversible actions; these principles are then applied to some special methods. Chapter 3 is devoted to the study of double decomposition of salts by the calorimetric method; chapter 4 presents the electrolytic theory of these reactions; in chapter 5 these two methods are compared, and the objections to the ionic theory are given in two classes, theoretical and experimental. Chapter 6 contains the theory of the general processes which produce complete precipitation, as far as possible, in double decomposition, and, inversely, which cause precipitates insoluble in water to become soluble. The concluding chapter is a study of some particular methods based upon double decomposition, and includes volumetric methods, gravimetric methods, and methods based on hydrolysis.

Emergency Surgery. For the General Practitioner. By John W. Sluss, A.M., M.D., Professor of Anatomy, Indiana University School of Medicine; formerly Professor of Anatomy and Clinical Surgery, Medical College of Indiana; Surgeon to the Indianapolis City Hospital; Surgeon to the City Dispensary; Member of the National Association of Military Surgeons. Second Edition, Revised and Enlarged; with 605 illustrations, some of which are printed in colors. Philadelphia: P. Blakiston's Son & Co., 1910.

This useful little work now appears in a slightly enlarged form. Among the new matter is a chapter on the general technique of laparotomy; spinal anesthesia is described in detail; and the sections on subphrenic abscess and pericardiotomy are enlarged. The work is intended for the general practitioner, and its main object is to serve him as a guide when he is confronted with difficulty or uncertainty in any surgical emergency. The book admirably fulfils its purpose; throughout, it is practical and clear; and the illustrations, if not always of the highest artistic merit, all serve some definite purpose and convey necessary information in the most direct and unmistakable manner. The general get-up of the book is attractive, and worthy of its contents.

Society Reports

CONNECTICUT STATE MEDICAL SOCIETY.

Annual Meeting, Held in New Haven, May 25 and 26, 1910.

(Special Report to the MEDICAL RECORD.)

(*Concluded from Vol. LXXVII, p. 1114.*)

The Treatment of Fractures.—Dr. GEORGE W. HAWLEY of Bridgeport said that the treatment of fractures had not kept pace with the advance of surgery and did not meet present-day needs. The enormous number of persons crippled every year as the result of fracture offered a challenge to surgical science. He thought that this industrial age would soon inquire what was being done to lessen this great industrial loss. In laying down the principles upon which treatment should be based, he said that there was room for common sense. As fractured bones tend to unite without assistance, the most that can be done is to help nature by approximating the ruptured tissues as accurately as possible. He saw a need for improvement in the means of holding divided bones in apposition, and in the technique of operations on fractures, based on the fact that bones stand trauma or infection but poorly. He saw no reason why an injured bone should not be repaired as readily as any other injured structure.

Dr. PHILIP D. BUNCE of Hartford said that the surgeon was judged to be the cause if the patient had any final disability or deformity after fracture, and that a monument of his skill existed as long as the patient lived. He thought that accurate replacement would give the best results, regardless of what kind of splint was employed, and stated that severe laceration of the soft parts often made the application of a splint or support very difficult. He did not approve of any method of fixation in which nails or drills were allowed to remain projecting through the skin, and said that *x*-ray pictures usually ought not to be shown to the patient.

Dr. WILLIAM H. CARMALT of New Haven was surprised at the pessimism of Dr. Hawley, compared with the optimism he himself felt in regard to success in the treatment of fractures. He thought that the principles of the care of fractures had not changed; and in these days of antiseptic surgery he saw no reason to hesitate to attack a bone that is in bad position and will give a bad functional result. He did not, however, think it worth while to cut down on every bone that the *x*-ray showed not to be in perfect position. One should let well enough alone if from experience one felt that the limb would prove useful.

Dr. SAMUEL M. GARLICK of Bridgeport considered it all very well to take the public into one's confidence when everything was all right, but not when things were not so right as one would like to have them. Professional confidence, he thought wise and safe, but he said that public confidence should be carefully scrutinized.

Dr. HAWLEY said that it had been impressed upon him that the large number of deformities following fractures was unnecessary. He thought that too much treatment was attempted in some cases, as a good many fractures required little or no other treatment than protection.

Some Principles of Intracranial Surgery.—Dr. WILLIAM H. VERDI of New Haven said that the greatest difficulty encountered was not in the surgical technique, but in the cerebral localization. One should not wait too long after making a diagnosis of increased pressure before instituting decompressive measures, owing to the danger of a loss of vision. He did not consider operations on the brain and cord any more difficult than operations elsewhere. In his whole series of cases he was obliged to stop but once on account of hemorrhages, and the only case of infection was that of a child operated upon at a private house, the wound being afterward infected. An operation for decompression is indicated in all cases that cannot be localized. While the results of operation for tumor of the brain were not so satisfactory as they should be, he considered the operation itself comparatively devoid of danger.

Dr. LEONARD W. BACON of New Haven related a case in which, after the withdrawal of the last piece of gauze from the wound left in the brain after the removal of a tumor as large as a turkey egg, there was a repetition of the pressure symptoms, the result being in doubt for several days, after which the patient went on to recovery. It was the first brain tumor removed in New Haven with the survival of the patient. He also related a case of very large brain abscess, in which the delay in operating had probably prevented the patient from recovering her vision.

Dr. MAX MAILHOUSE of New Haven had suggested to Dr. Verdi that in a case of cerebellar tumor in which there was marked bulging from the great intracranial pressure, a slight incision between some of the laminæ might permit the pressure to extrude the growth. This actually took place, and he thought that the same procedure might equally well be pursued in other areas of the brain. While opinions based solely on the presence of pain and choked disk were sometimes erroneous, as specific disease might give this picture as well as tumor, Dr. Mailhouse thought that when the optic disks were in such a condition as to threaten vision, the safest procedure for the patient was at least a decompression. The unilateral dilatation of the pupil is often an aid in localization, and unilateral convulsions are still more valuable in this respect. In the prognosis of the results after operation one should be guarded.

Dr. WILLIAM H. CARMALT of New Haven said that Dr. Mailhouse's last remark had led him to speak of a case of operative infiltrating glioma of the cerebellum in a patient previously operated upon unsuccessfully for decompression. The boundaries of the tumor were not made out, but no recurrence took place.

The Treatment of Tuberculous Patients Outside the Sanatorium.—Dr. DUDLEY B. DEMING of Waterbury said that treatment of patients in the social station in which tuberculosis abounds could not be carried on so well outside the sanatorium as in such an institution. Sanatoria, however, should not admit only incipient cases, while rejecting advanced ones and discharging those that fail to improve. The latter became advanced cases, and spread the disease. The prevention of tuberculosis would require the expenditure of vast sums of money to care for advanced and chronic cases in sanatoria, and to aid families thus deprived of their wage-earners.

Dr. DAVID B. LYMAN of Wallingford said that there was no case of tuberculosis that did not have to be treated outside the sanatorium, because practically all that this institution did was to arrest the disease, the patient requiring treatment for years after returning home. He must be watched for years in order to make sure that his anatomical tuberculosis does not develop into a clinical one. The most dangerous point in the case is when the patient looks and feels perfectly well, but yet has an anatomical tuberculosis. He should be instructed to come to the physician for examination at regular intervals, whether he is feeling badly or not. Dr. Lyman thought that a light indoor occupation was not so bad for such patients as it had been considered, if the doctor could regulate the fourteen hours not spent at work. He approved of the use of a sleeping porch, when possible, but did not believe in overfeeding or forced feeding, which he thought caused most of the stomach symptoms.

Dr. HENRY F. STOLL of Hartford said that if the patients would go to bed at half-past seven, a good many would get well and stay well under home treatment. He thought that extremely good results could be obtained in private

patients with tuberculin, which relieves the toxic symptoms. Patients that take tuberculin relapse less frequently and live longer than those who do not. Great harm can be done with it, however, if not properly used.

Dr. I. E. Brainard of Wallingford remarked that the handkerchief that the patient holds before his mouth when he coughs should be well taken care of afterward, and not stuffed into the pocket with damp sputum on it.

Dr. Erastus P. Swasey of Hartford said that outdoor treatment was not beneficial in his part of the country at some seasons, owing to the high winds, which fill the atmosphere with dust.

Dr. Deming replied that even when it injures the patient the advantage of keeping him out of doors is the lessened risk of exposure to the other members of the family. He thought that a piece of gauze sufficiently thick not to be quickly wet through was better than a handkerchief, as it could be burned.

Some Features of Rectal Alimentation.—Dr. Louis M. Gompertz had conducted some experiments in order to determine the absorptive power of the rectum. He had found salt absorbed almost as completely as when given by the mouth. Dextrose was either all absorbed or disappeared through fermentation. Fat was not tried. The author said that as nutrient enemata do not reach the small intestine, proteins, when not predigested, simply putrefy in the large intestine and pass out as feces. If dextrose were absorbed in sufficient quantity, it would take the place of protein. A little over one-third the number of calories necessary to sustain the body at rest was daily furnished by the dextrose. He concluded that the rectum is capable of absorbing water, sodium chloride, and dextrose solutions in the form of rectal enemata. Therefore, he considered rectal enemata useful in sustaining the body in emergency, preventing complete starvation for a short period.

Dr. Lafayette B. Mendel of New Haven said that as our knowledge of the physiology of the alimentary tract has been greatly extended, it ought to be possible to introduce anew such features of rectal alimentation as are promising in principle and susceptible of clinical application. Observations like those of the author emphasized the helpfulness that came from being able to measure in some way the results that any therapeutic procedure accomplished.

Dr. Charles J. Foote of New Haven remarked that a nutrient enema was a makeshift, designed to meet an emergency, and could not be used for any length of time. It was not intended to build up the body, but merely to prevent retrogression. Dextrose, he stated, is absorbed rapidly, and furnishes heat and energy, while protein, being absorbed less rapidly, does not furnish energy so quickly. He could not, therefore, see the advantage of using it, even when predigested. He stated that alcohol took the place of dextrose to some extent. He thought that one should be on one's guard concerning the absorption of salt in cases of uremia. He had seen instances in which large quantities of the saline had been taken readily in uremia, but in which, as there was a small excretion of urine, a great deal of the salt solution was retained in the system, the patient becoming waterlogged and developing edema of the lungs.

Dr. Frank P. Underhill of New Haven remarked that it was a mistake to think that because rectal enemata could not supply the whole 1,800 calories there was no use in giving any. He thought that half a loaf was better than none.

Dr. Walter L. Barber of Waterbury attributed the cure of his wife from a serious condition in which she could retain nothing on her stomach to the use of rectal enemata containing milk, beef juice, whiskey, and quinine.

Dr. J. F. Calef of Middletown believed that in cases of the vomiting of pregnancy of the severe type there was, more than any other disease, a reversed peristalsis that might carry rectal alimentation into the stomach. He mentioned a case in which he was sure that this had occurred.

Dr. Elias Pratt of Torrington asked whether Dr. Gompertz had made any experiment with predigested protein in connection with the dextrose.

Dr. Gustavus Eliot of New Haven stated that he had found a preparation of milk, partly peptonized by the addition of bicarbonate of soda and extract of pancreas, very beneficial in overcoming the difficulty often experienced in getting these enemata retained.

Dr. Gompertz stated that he had used predigested protein in days gone by, but had had no analyses of the feces made in these cases, so he did not know whether these enemata were absorbed or not. As patients can live for weeks with only water, feeding on their own tissues, and as no accurate measurements were made in the case spoken of, he thought it very doubtful whether any nutrition was furnished by the milk.

Chronic Family Jaundice.—Dr. Wilder Tileston of New Haven described this disease as characterized by chronic icterus of moderate intensity, with enlargement of the spleen and anemia. It is usually hereditary; less often familial or acquired. Males and females are affected with equal frequency. The jaundice is of the non-obstructive type, with well-colored stools, and absence of bile in the urine. There is usually a marked urobilinuria. The spleen is markedly enlarged; the liver, only slightly so. The patients suffer frequently with "bilious attacks," gallstone colic, and nose-bleed, but are otherwise fairly healthy and live to a good old age. The red corpuscles are abnormally fragile. The prognosis is good as to life, but absolutely bad as to recovery. Treatment should be confined to general hygiene. Iron may be tried for the anemia. The presence of colic is an indication for the operative removal of the gallstones. Dr. Tileston presented reports of thirteen cases occurring in four families.

Dr. George Blumer of New Haven stated that when the patients are first seen at night it is not always possible to make out the jaundice. They should be seen again by daylight. He asked whether Dr. Tileston had seen any suggestion of a relation between this disease and paroxysmal hemoglobinuria, another disease in which there is excessive fragility of the red blood corpuscles. While other forms of hemolytic jaundice had been described, Dr. Blumer did not know of any statement to the effect that there was an absence of bile in the urine in these other forms. He thought that this disease might be confused with Gaucher's disease, in which there is also family enlargement of the spleen, but not usually associated with jaundice.

Dr. Tileston did not think that there was a very close relationship between chronic family jaundice and paroxysmal hemoglobinuria. Regarding the absence of bile in the urine in other types of hemolytic jaundice, he said that there was usually no bile, but only bilirubin; although sometimes there was a small amount of bile. As eleven of the twelve reported instances of Gaucher's disease were in females, he did not think it likely to have been Gaucher's disease in his cases.

Periodic Attacks of Indigestion in Children.—Dr. Walter G. Murphy of East Hartford stated that diacetic acid was the result of the intestinal decomposition of food. Various theories had been suggested associating diacetic acid with cyclic vomiting and recurrent attacks of indigestion. The exciting causes of the attacks of vomiting were fright, excitement, fatigue, anger, exposure to cold, and similar influences acting through the nervous system. Many argued that the attacks were not due to errors in diet. Acetone might be present in other conditions, and the

neurotic and rheumatic aspects must be recognized as contributing causes. He believed that the condition was a neurosis, toxic in character, based upon a defective nervous control, the result of an inherited unstable and irritated nervous system. The author said that if this idea were correct, treatment should be directed to the cause, and not to the result. He thought that most children were neurotic and anemic, and that, on account of their digestive troubles, they were often underfed. He considered that a full and generous diet should be given them. On the appearance of symptoms of an attack, food should be stopped, and the digestive tract thoroughly cleaned out with castor oil. Repeated doses of sodium bicarbonate should also be given.

Dr. Frank P. Underhill of New Haven said that there was little doubt that the symptoms described by Dr. Murphy were dependent upon defective nervous control. It was well known that a child was much more easily put into a condition of defective nervous regulation than an adult. Excessive putrefaction in the intestine might serve as a stimulus for this in those neurotic and undernourished subjects. He did not think that the presence of diacetic acid in the urine in these cases should be over-emphasized. Acetone bodies probably arise within the body as the result of the incomplete combustion of fats, and Dr. Underhill believed that the diacetic acid was neither the cause nor the direct result of the pathological condition under discussion. He ascribed the presence of this substance in the urine to the condition that accompanied the abnormal manifestation, viz., the under-nutrition, in which it could be easily demonstrated that diacetic acid was always present. Young children could be thrown into a condition of acidosis with extreme ease, and a moderate degree of acidosis, especially in children, should not be regarded as a grave symptom.

Dr. Charles A. Goodrich of Hartford considered that we should also bear in mind certain intestinal disorders in children in which there was, besides cyclic vomiting and convulsions, a certain nervous phenomenon that resembled the beginning of diabetic coma in adults. In a good many cases of these digestive attacks the diet apparently did not influence the condition; the children, consequently, became increasingly malnutrient.

The Relative Value of Symptoms, Physical Signs, Tuberculin, and the X-Ray in the Diagnosis of Tuberculosis.—Dr. Henry F. Stoll of Hartford said that in tuberculin we have a diagnostic aid of accepted value, if used in conjunction with the symptoms and physical signs. He considered the *x*-ray of great assistance in the diagnosis of pulmonary conditions. The negative must not only be perfect, but the interpretation thereof was of value only when made by one who had had a large experience in this particular field. He said that incipient cases that had been carefully examined rarely came to post mortem, and that much could be learned by a comparison of the physical signs and the *x*-ray findings in a series of early cases. In deep-seated lesions, the *x*-ray sometimes demonstrates a lesion that does not give physical signs.

Dr. William B. Bartlett of Hartford emphasized the difference between anatomical and clinical tuberculosis. Physical signs, tuberculin, and the *x*-ray, if without symptoms, may all three be disregarded; with symptoms, the diagnosis of tuberculosis may be made, even though the signs, the *x*-ray, and the tuberculin test are negative. The importance of malaria in the past history should be emphasized, and among symptoms he considered pain very important. He stated that râles at the base were most frequently due to other causes than tuberculosis. A positive tuberculin reaction, he thought, did not mean clinical tuberculosis. He said that the subcutaneous method of using tuberculin was the most reliable, but that even this might occasionally be at fault.

Dr. David R. Lyman of Wallingford considered Dr. Stoll's comparison of the relative value of these four means of diagnosis showed that not one of them was of such supreme value that physicians could afford to leave everything else out of consideration, and said that the only thing that Dr. Stoll had not mentioned was the constant occurrence of little localized dry pleurisies in these cases. He considered tuberculin one of the most powerful of poisons, but had never seen ill effects from its subcutaneous use in small doses. He did not, however, think it necessary to employ it, if the diagnosis could be made without it, and the patient was willing to accept his opinion and act upon it. He did not approve of the eye-test, and he thought that there was no question but that an expert could discover with the *x*-ray deep-seated lesions that an ordinary person would miss.

Dr. F. S. Crossfield of Hartford stated on behalf of the laryngologists that in the early stages of pulmonary tuberculosis there were absolutely no pathognomonic symptoms in the larynx.

Dr. J. B. Griggs of Hartford did not consider the positive tuberculin test valuable, but said that the negative one was.

Dr. Stoll reiterated that if the tuberculin test was negative the possibility of the presence of tuberculosis was very slight, but stated that it did not exclude the disease. He stated that, long before the invention of the stethoscope, physicians diagnosed tuberculosis correctly by means of the symptoms. It was unusual to have the physical signs disagree with the diagnosis made from the history and the symptoms.

The president's annual address was delivered by Dr. Samuel D. Gilbert of New Haven.

Officers.—The following officers were elected to serve for the ensuing year: *President*, Dr. Frank K. Hallock of Cromwell; *Vice-Presidents*, Dr. Edmund P. Douglas of Groton and Dr. E. T. Bradstreet of Meriden; *Secretary*, Dr. Walter R. Steiner of Hartford; *Treasurer*, Dr. Joseph H. Townsend of New Haven. The society will meet next year at Hartford, on the fourth Wednesday and Thursday in May.

AMERICAN MEDICAL ASSOCIATION.

Sixty-first Annual Meeting, Held in St. Louis, June 6, 7, 8, 9, and 10, 1910.

(Special Report to the Medical Record.)

(*Concluded from Vol. LXXVII, p.* 1111.)

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Third Day—Thursday, June 9.

Dr. J. G. Clark of Philadelphia, Chairman.

Dr. Horace G. Wetherill of Denver was elected chairman of the section for 1911.

Tuberculosis of the Female Organs of Generation and the Peritoneum.—Dr. J. Riddle Goffe of New York read this paper, describing the two types of tubal infection: ascending, primary from infection of the mucous membranes of other parts of the genital tract, and secondary lymphatic invasion following traumatism or absorption from the peritoneum. The probability of infection of the female from the male by the seminal discharge was not great. The puerperium and lacerations favored infection, as did also catheterization. The diagnosis was to be made only on finding the tubercle bacillus. In nearly three thousand cases reported from New York City less than one per cent. of the cases had shown tuberculosis. A radical operation was the only efficient treatment in tuberculosis of the female generative organs, and the operation should be as radical as in cancer. The cases of tuberculous peritonitis were rarely of hemic origin, more frequently subsequent to tuberculosis of other abdominal or-

gans, and infected either by contiguity or direct extension. A certain number of cases got well spontaneously. In others the surgeon could assist nature. The kind of treatment depended upon the pathology of the condition; whether ascitic, adhesive, or cheesy type of exudate. In the ascitic cases the fluid should be evacuated and the abdomen promptly closed without handling the contents of the abdomen and without drainage, although any evident focus might well be removed. In the adhesive type no interference was desirable unless some evident focus could be removed. No drainage was desirable. In the stage of caseation while resection of the intestine and extensive operation was not desirable yet a rubber drain (never a gauze drain) might be allowed. Surgery got the best results in the ascitic type, but did little to remove adhesions. He described a case where a young woman four years ago had a primary apical tuberculosis. A year later on account of abdominal distention tuberculous peritonitis was diagnosed. An exploration revealed a peritoneum three-eighths of an inch thick, with fluid and adhesions. The abdomen was closed without drainage, but the incision broke down and the wound began discharging fluid and pus. The patient was treated with full hygienic care with slight improvement, but a year brought a return to normal weight and strength, though the fistula still remained.

Dr. Novak of Baltimore called attention to the importance of always considering tuberculosis in every abdominal mass.

Dr. Frederick of Buffalo said that the cases of acute tuberculous peritonitis did not always survive the operation, but did usually recover. For four or five years he had been draining all cases through the cul-de-sac of Douglas after breaking up all adhesions and exposing all tuberculous surfaces. The drainage tube was kept *in situ* for many months, and recovery followed in nearly every case.

Dr. Gilmore of Chicago had had three cases of tuberculosis of the tubes in the past few months. They were all secondary cases, and gave the same general symptoms as tuberculosis in other regions. He laid great stress on the von Pirquet reaction, which he considered as safe negative evidence if the test was negative, while a positive reaction was of doubtful value. Leucopenia also was suggestive of tuberculosis.

Dr. Byford of Chicago doubted the value of free separation of adhesions, which were nature's process of limiting the infection. He thought that drainage could be effectual only for two to three days, and then over a limited area. He believed in letting in air and perhaps increasing congestion by sprinkling the intestines with chloroform. Primary foci should be removed if feasible. In many cases it might be wise to remove the ovaries, whether they were involved or not, in order to avoid the subsequent monthly congestion of the pelvic organs.

Dr. Gilliam of Columbus had excellent results in operations on the cases of tuberculosis with effusion. Even if the fluid did reaccumulate early a cure might still follow. He did not believe in interfering in the other cases. The adhesions should be let alone, and no drain should be used. He had never found a tuberculous fistula to heal. If many adhesions had to be separated to remove a primary focus, it was better to leave in the focus.

The Participation of the Glandular System and Tissues Adjacent to the Uterus in Carcinoma of the Uterus.—Dr. J. A. Sampson of Albany read this paper. First he noted the differences between cancer of the body and cancer of the cervix of the uterus. Cancer of the body was infrequent, occurred in the old and the multipara. It was of slow growth, of low mortality, and had many cures. Cancer of the cervix was one of the most frequent neoplasms, it was more common in youth than in old age, and rapid in growth, and early involved other tissues and nodes. Hysterectomy for cancer of the cervix was followed by a high mortality and few cures. The remarks were confined to cancer of the cervix. The origin of the growth was either in the mucosa of the cervical canal or on the vaginal portion of the cervix mucosa. The vaginal mucosa origin tended to produce an everting type, was less common, and less malignant. The canal mucosa type tended to produce an inverting growth, invading the deep tissues of the uterus rather than extending over the mucosa, and then the cancer masses, sloughing out, gave crater formation in the cervix. In this type also the lymph nodes were early invaded. Additional danger arose from the proximity of the bladder, ureters, and lymph nodes to the point of origin of the cancer in the cervical canal. The fibrous sheath of the ureter, however, seemed to give it a certain amount of temporary protection from the invasion from the cancer, possibly on account of the density of the tissue, or on the different sets of lymph vessels made necessary by the peristaltic motion of the ureter. As a rule the ureter was compressed before it was invaded by the cancer. This sheath of the ureter also allowed it to be shelled out free from the cancer in a certain number of cases. Of 41 cases operated on for cancer of the uterus, the bladder was invaded in 8; while of 12 ureters examined only 1 was invaded. In one-third of the cases operated on the lymph nodes were involved at the time of operation in one-third of the cases. One node where the ureter crossed the iliac vessels was very frequently involved. New formed lymph nodes in the lymph vessels seemed to check the spread of the cancer. In three cases all the abdominal and pelvic nodes removed were involved, even beyond where they were usually removed. In over half of the cases operated on the growth had extended into the abdominal nodes. Hence "recurrence," so called, was probably but a continuation of growth in unremoved tissues that were already involved. Such was the usual condition in the vaginal recurrences. An increase in connective tissue tended to obliterate the lymph spaces and limit the spread of the disease. Whether a growth could be operated on hopefully or not could not be told until operation, as the induration of the parametrium was not proportionate to the extent of the disease. It might be due to inflammatory infiltration. The most radical operation that the patient would stand was indicated in every case. In over half the cases there was a history of neglected bleeding for over six months, so that it was desirable to educate the physician, and through him the laity, until the first signs of bleeding were recognized as suspicious of cancer of the uterus.

The Results Obtained by the Radical Abdominal Operation for Carcinoma of the Uterus.—Dr. J. H. Jacobson of Toledo gave some statistics on this point. The determination of whether or not a case could be operated on safely could only be determined after opening the abdomen, but in general the Europeans considered 65 per cent. operable, while the Americans would operate only on 35 per cent. Possibly this was due to the campaign of education that had been going on in Europe. The primary mortality in Europe was 20 per cent., while in America it was but 15 per cent. But the cures of five years' duration in Europe were much larger—40 per cent.—in America, but 8 per cent. The principal causes of the primary mortality were sepsis and shock.

The Diagnosis of Operability of Carcinoma of the Cervix Uteri.—Dr. Emil Ries of Chicago discussed this point. The personal equation always was very important in these cases. Some surgeons would never operate. Some operated to get a low primary mortality, but this gave a high secondary mortality. Some men did a radical operation and got a high primary mortality but a low secondary. Some patients neglected themselves, others were neglected

by their family physician. Personally, in the past ten years or so he had seen 33 cases, 11 of which were inoperable and 22 had been operated on. He had done an extremely radical operation in each case, with the patient's consent, and appreciation that an operative death was preferable to a cancer death. Ten of the 22 had died from the immediate effects of the operation through sepsis, hemorrhage, effect of anesthetic, or other cause. Of the twelve completed operations one case was a cancer of the body which was in a different class from the others. One was known to have been alive ten years after the operation, and all the others were still known to be alive and without sign of recurrence. The operability of a case could be determined only by the preliminary examination, a further examination during the operation, noting the condition of liver, spleen, aortic and iliac glands, broad ligaments, and parametrium; and finally by the microscopic examination of the tissues.

Further Observations on the Use of the Cautery in the Treatment of Cancer of the Uterus.—Dr. C. C. Frederick of Buffalo called attention to the value of high rectal examination and the significance of pain. Pain with cancer indicated that the nerves had already been involved. In treatment he regarded the actual cautery as very hopeful and preferable to the chemical cautery, as the deep hard scar extending into the tissues tended to prohibit the later growth of the disease. The cautery controlled the hemorrhage and the infection, and got rid of the fetor of the discharge. The mass of the growth should be curetted away and then the surface dried and cauterized, the cautery being brought near but not touched to the tissues. This radiation cauterization gave greater penetration, as the heat was higher. Care should be taken not to cause penetration of bladder, ureters, or rectum. A secondary hysterectomy might be advisable after the cauterization.

Dr. Gelhorn of St. Louis agreed with Dr. Frederick that the cautery relieved symptoms, but found that repeated cauterization was desirable every few weeks. Personally, he used acetone hardening, which gave deep penetration and kept the patient alive for one or two years in comfort. He curetted away the mass of the tissue and inserted a speculum into the crater thus formed, pouring acetone into the speculum and leaving it in contact with the tissues for twenty to thirty minutes; then he packed the crater with acetone gauze. Applications were made three times a week, and the tissues were rendered so hard that they could not be scraped away with the curette. The subjective improvement of the patient was marked.

Dr. Peterson of Ann Arbor praised the thorough work of Dr. Ries, in spite of the high mortality. Personally, of seven operated on, he had four cases alive more than five years after radical operation. Of those four, two were carcinoma of the body, but even those had not been easy for him to save. Since the less radical removal of glands had been undertaken the primary mortality naturally had been less. Of 22 cases that he had operated on less radically, only 1 had died primarily from the operation and 10 were alive two to three years after the operation. He considered that certain cases were excluded from a radical operation independent of the stage of the growth; such, for instance, as the very obese.

Dr. Goldspohn of Chicago called attention to the frequency of recurrence at the cervicovaginal juncture, which should be removed, and preferably by the combined abdominal and vaginal operation. The hysterectomy to the point of severing the vaginal connection of the uterus should be done from above and then the abdominal part of the operation completed and the removal of the uterus and masses should be done from the vagina, pushing the enucleated uterus down from the abdomen. This allowed much freer excision of the vagina than by either route separately. He considered repeated cauterization hopeful in some of the cases that seemed inoperable.

Dr. Eliza M. Mosher of Brooklyn called attention to the campaign of education that was being carried on in New York to educate the laity as to the importance of early diagnosis in cancer.

Dr. Ries noted that of the cases in which the glands were radically removed and studied, 60 per cent. showed cancerous invasion of the glands at the time of operation. Wertheim said that of the cases with gland involvement at the time of operation, all had recurrences.

The Place of Hebosteotomy as an Aid to Delivery.—Dr. C. W. Barrett of Chicago said that a disproportionately large head of the child in a small pelvis of the mother was a menace to the fundamental principle of pregnancy, which involved the continuation of the life of the mother and the reproduction of another living being. That while pregnancy and labor normally were physiological, yet in pathological cases the duty of the obstetrician should be to save both lives, if possible, and the cases of marked contraction of the pelvis should not cause 100 per cent. mortality of the infant. And the fact that the fetal head remained high above the pelvis late in labor did not always indicate a cesarean section. Enlargement of the pelvis had its distinct place. Williams had reported 25 cases with no deaths to mother or child, and Barrett had had 6 cases with no loss of mother or child. In 4 of the author's cases forceps had been applied without success prior to the hebosteotomy. One of the cases had been in labor for four and a half days. The operation was associated with no greater laceration than was common to forceps delivery, and no annoying hemorrhage. The first case had been done by the open method, cutting cartilage and bone, and the other five by the subcutaneous method, cutting bone. There had been no later bony separation in any of the cases. The reported injuries to bladder, urethra, and possibly to the head of the child had been due to the use of a sharp needle in inserting the saw. The indications for hebosteotomy were those cases of contracted pelvis, where cesarean section was not the choice on account of possible infection. The ideal conditions were those of moderate contraction of the pelvis, in which there had been a fair promise of delivery without any operation but the mother was becoming exhausted. The aseptic restrictions were not as strict as in cesarean section. Prior to operation, thorough massage of the soft parts should be made, to allow additional separation of the soft tissues without tearing. A puncture was made in the angle between the labia majora and the labia minora and the ligature carrier with a large curve and a blunt point, especially adapted to this operation, was inserted into the interlabial puncture and made to penetrate directly to the bone. Then its top was kept in contact with the bone and carried under the symphysis to the upper margin of the bone and there brought out through the skin of the mons veneris. A silk ligature was then pulled back with the ligature carrier and a Gigli saw pulled through with the silk. Then the bone was cut and delivery proceeded with. This cutting of the bone allowed separation of from two to six centimeters. In version cases it might be well to lay the silk ligature preparatory to the saw before doing the version, so that if the after coming head should lodge, the bones could be quickly cut and separated.

Dr. Zinke of Cincinnati had urged this operation some years ago without support, and was glad that it seemed to be finding favor. He thought that all cases of contracted pelvis should go to hospital for delivery and labor tried normally. If the patient was unable to deliver herself, in the cases of moderate contraction hebosteotomy should be done, and in the cases of extreme contraction cesarean section should be done.

Dr. Foulkrod of Philadelphia considered the dangers of hebosteotomy great enough to give it few indications.

The dangers of hemorrhage and laceration were great. At Jefferson Hospital it was the custom to let the woman go into labor, and if she could engage the head forceps were applied, while if she could not engage the head cesarean section was done. He considered that there were a number of cases of infected uteri and gangrenous uteri in which hebosteotomy would not be safe, but cesarean section and removal of the uterus would save the life of the mother.

Dr. Fry of Washington, D. C., considered the painful convalescence to be one of the greatest objections to the operation. The great pain on moving the patient's pelvis after the operation was always to be considered. He would consider the operation never one of choice, though it might be indicated after a long test of labor with probable infection of the uterus. His experience with high forceps and version for contracted pelvis had given an infant mortality of about 33 per cent. He had done hebosteotomy with the mons veneris puncture first, and the labial puncture as the point of exit. In sawing through the bone he considered it desirable to hold the pelvis so as to support the bones at the time of separation to avoid snapping of the bone.

Dr. Burns of Denver considered symphyseotomy simpler; it needed no special instruments, could be done in a private house, and the patient could get up on the tenth day.

Dr. Barrett, in closing, said that the advantage of cutting the bone was the less danger of injury to the crus of the clitoris and to the urethra. The subcutaneous operation was quicker and less liable to infection than the open method. Holding the bones at the time of sawing was not necessary, as there was very little primary separation of the bones. The trying test of labor came only after rupture of the membranes. He considered the operation especially desirable in the very late cases and when the patient could not be moved to the hospital.

The Etiology of Eclampsia.—Drs. E. P. Davis and Collin Foulkrod of Philadelphia presented this paper. They considered eclampsia as a distinct disease of which the toxemia was the essential basis. In the toxemias a chemical cause due to perversion of metabolism was sought in a study of the excretions. The decrease in the urea nitrogen with an increase of the ammonia nitrogen showed a deficient disamidization (breaking down of the ammonia element rather than a mere deficiency in oxidation.) The breaking down of the ammonia took place in the liver, so that a lesion was to be sought in the liver, but the changes in the liver were not the primary changes as kidney changes were found out of proportion to the liver changes in certain cases and thyroid administration seemed to help certain cases, showing, also, a thyroid involvement. It seemed to have been shown that the primary cause of the trouble lay in the placenta and the fetus. The placenta was full of ferments essential to the interests of the fetus and balancing the activities of the mother. And when these placental ferments were upset the mother's balance of metabolism was upset. No special toxin could be found causative of eclampsia. The characteristic symptoms were lassitude, stupor, coma, or mania, headache, dry tongue. There occurred crises of convulsions, explosions of pain, in the head or chest, gastric and intestinal irritation, pernicious anemia, hemorrhages into retina, mucous membranes, retroplacental, and cerebral. There was no fever, but the blood pressure rose early to perhaps 180 millimeters. The daily output of urine was lowered, the quantity of urinary solids lessened, and the proportion of the nitrogen factors changed. The presence of albumin in the urine was not essential. The presence of indican and of casts showed the need of great care.

Treatment of Eclampsia, Including a Comparison of the Dangers of Chloroform and Ether in This Condition.—Drs. E. B. Cragin and E. T. Hull of New York presented this paper. It was generally recognized that in the treatment of toxemia threatening eclampsia that the products of metabolism requiring elimination should be reduced, that elimination of the metabolic products should be favored, that high blood pressure should be reduced. That, if the toxemia did not markedly improve under these lines of treatment, or if an eclamptic seizure supervened, that the uterus should be emptied. That injury to the patient's tissues should be avoided. The reduction of the metabolic products requiring elimination should be done through avoiding meat in the diet. Chicken and fish were allowable, but red meat should not be eaten more than two or three times a week. The elimination should be favored by increasing the activity of the skin, drinking large quantities of water, and taking calomel. Colon irrigations were very useful. The high blood pressure was to be reduced by blood letting or the administration of drugs such as chloral in an initial dose of thirty grains followed by twenty grains every four hours, if necessary, nitroglycerine in large doses, and, if necessary, veratrum viride after the chloral, given in five minim doses of the fluid extract until the blood pressure fell and the pulse rate was about one hundred. If the urine, blood pressure, and general condition did not improve, the uterus should be emptied. In emptying the uterus care should be taken not to reduce the activities of the organs or the patient. Manual dilatation and version was the method of choice if the cases were feasible, but with the rigid cervix the bag dilators avoided much of the shock and laceration. In very urgent cases the vaginal cesarean section might be the choice. Formerly it had been the custom to administer chloroform to prevent the convulsions, but chloroform had been shown to be a very harmful remedy. The pathological lesions produced by eclampsia and by chloroform being very similar, in the congestion, hemorrhage, and necrosis of the various organs of the body. The liver lesions were responsible for vomiting and jaundice; the kidney lesions for headache, and troubles with the central nervous system. Chloroform lesions in the cases of acute and delayed poisoning were both of the same type and might follow the administration of chloroform for only twenty to thirty minutes. In some of the late cases there developed merely pallor, or cyanosis, stupor coma, and death. In dogs killed by ether by one administration and after repeated administrations of two to three hours' duration on successive days no suggestion of the cellular necrosis in liver and kidneys or other organs was found. Hence, the chloroform in itself was the cause of injury to the essential eliminative organs and should not be administered in cases of eclampsia. In the last twenty cases at the Sloane Maternity Hospital, ether had been used in place of chloroform for all operations. The mortality was one case, 5 per cent. In the preceding twenty cases in which chloroform had been used the mortality had been 25 per cent. In a long series of eclampsia cases in which chloroform had been given the mortality had been 28 per cent.

Vaginal Cesarean Section in Eclampsia.—Dr. H. D. Fry of Washington read this paper, saying that the objections to the operation were mainly theoretical. The time for the operation was as short as for the classical cesarean section. The abdominal section was used for many other conditions than eclampsia so that comparison of the results of the two operations was not a fair one. The injury caused was no greater than by other means of delivery for the same men, and subsequent labors were followed by no complications due to this operation.

Indications for, and Technique of Rapid Emptying of the Uterus in the Toxemias of Pregnancy.—Dr. Reuben Peterson of Ann Arbor read this paper. He considered

that vaginal cesarean section was indicated where the pelvic bones were normal, the child not too large to pass the bony structures, and quick delivery essential in the cases of eclampsia with a rigid cervix, and in country practice. In doing the operation the vagina was dilated the cervix caught in a volsellum and brought down in sight, an incision made around the front half of the cervix at the cervicovaginal junction. No longitudinal incision in the mucous membrane was necessary. Then the bladder and soft tissues were dissected free from the anterior surface of the uterus, largely by pushing the tissues up with a sponge. Then two volselli were inserted in the cervix laterally and the cervix split in its anterior lip with scissors up seven to nine centimeters until the hand could be introduced. In pregnancies after the eighth month, a similar posterior splitting of the cervix was usually necessary by a transverse incision in the mucosa, sponge dissection of uterus free from rectum and other soft tissues, and splitting the posterior lip of the cervix with scissors. In closing, the catgut sutures were introduced not entering the cervical canal, but through the submucosa and embracing all the deep tissues of the cervix out to the surface of the uterus that had been dissected free from the vaginal mucosa. After the uterus had been sewed up, the vaginal mucosa flap was closed protecting the deep sutures.

The Surgical Treatment of Eclampsia.—Dr. J. B. DeLee of Chicago said that the presence of eclamptic convulsions was one sure indication for emptying of the uterus. Before the fetus was viable perforation and extraction was the method of choice. After viability, if the os was dilatable version and extraction was indicated. In the cases with a rigid cervix manual dilitation was allowable only in certain easy cases, the bag dilatation was applicable only where there was no need of rapid delivery, as it took several hours for dilatation; and the vaginal cesarean section gave the best results. The vaginal section was not as easy to perform as the abdominal, but the mortality in the eclamptic cases was higher. Not only did the rigidity of the cervix have to be considered but also the rigidity of the pelvic floor and of the vagina. Decapsulation of the kidneys was not a rational line of treatment as the condition was not one of pure renal origin. As an anesthetic morphine had a marked effect on the fetus, chloroform had a very serious effect on the mother. Nitrous oxide and oxygen was the choice.

Dr. Schwartz of St. Louis said that the bad effects of chloroform had been most clearly shown and the great advantage of more careful observation of the women during pregnancy was most desirable. Regulation of the diet and full elimination should be watched in every case.

Dr. Zinke of Cincinnati thought that the great reduction in the fatalities from eclampsia had been made, not by surgery, but by the early medical care. The surgical treatment made no attempt to reduce fetal mortality, but worked solely for the maternal mortality. He quoted certain lines of treatment in vogue in Germany based on absolute rest from external influences as evidence that certain cases recovered spontaneously even after a long series of eclamptic convulsions.

Dr. Carstens of Detroit considered the sole duty of the physician in the case of eclampsia was to deliver the woman by the best possible means, which, in the majority of the cases seemed to be by the vaginal cesarean section

Dr. Plondke of St. Paul noted the cases of postpartum eclampsia in which the removal of about a quart of blood followed by infusion of an equal quantity of salt solution gave a prompt and decided improvement possibly by dilution of the toxins in the blood.

Dr. Burns of St. Louis thought cesarean section, but not hysterectomy, was indicated in the infected cases.

Dr. Rosenthal of Fort Wayne called attention to the limitation of the lacerations in the vaginal section to the median plane of the uterus, and said that the lateral lacerations were more apt to be serious.

Dr. Ritter of Indianapolis considered the early medical treatment as preventive and therefore most desirable. He used veratrum viride and gave doses of ten to twelve minims of the tincture. He had also gotten good results from bleeding and infusion.

Dr. Foulkrod of Philadelphia said that the early preventive treatment was most desirable, keeping the patient on a milk diet and absolute quiet. That the Murphy treatment of lavage and enteroclysis was at times very effective. That better results were obtained from venesection after delivery than before.

Dr. Hull of New York said that bleeding had formerly been used at Sloane, but that it had been superseded by the use of vasodepressants pushed to the point of physiological effect. That after the blood pressure was down and the pulse slow no convulsions followed. That while venesection was rarely needed, that free bleeding with the delivery of the placenta was encouraged by manual extraction of the placenta.

Dr. Fry of Washington called attention to the fact that one of the leading obstetricians of this country, Dr. Hirst, was taking up the medical treatment to the exclusion of the emptying of the uterus. In the operation of vaginal cesarean section he had found the uterovesical ligament at times to be a great interference. He drained all the cases. In regard to the use of chloroform he cited a case of late chloroform poisoning following a forceps delivery after about an hour of chloroform. There had been no symptoms of disturbed metabolism during pregnancy as shown by repeated careful urine examinations, but the third day after delivery she developed a stupor that deepened steadily to death.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held April 28, 1910.

Dr. S. M. Brickner in the Chair.

A Preliminary Report Upon the Use of Oxygen in Asphyxia Neonatorum.—Dr. Frederick C. Holder said that asphyxia neonatorum was a condition of oxygen starvation plus carbon dioxide poisoning, produced by numerous causes. The two types, the livid and the pallid, were different degrees of the same process. Owing to the better understanding of obstetric indications, many of the causes of asphyxia, as well as destructive operations upon the fetus, were things of the past. The Schultze method, although often used to overcome this condition, was not without danger, as was shown by instances of fractured clavicle with perforation of the lung, dislocation of the shoulder, ruptured liver, and injuries resulting from the slippery infant escaping from the hands and falling against the floor or wall. Direct insufflation was open to the criticism that the inspired air was loaded with carbon dioxide and numerous germs. Sylvester's method was rarely effectual, and it was a waste of time to use it. Two years ago Dr. Holder began to use oxygen for this purpose. He held the child in the inverted position with the left hand, after having wrapped a towel around the feet to prevent slipping. The mucus was removed from the mouth and nostrils, and if it was very abundant an assistant compressed the chest while the child was still in the inverted position. The back was then rubbed or slapped, and if the child failed to breathe or cry the cord was cut. The infant was then tubbed in water at a temperature of 105° F. and the method of Byrd followed. This method consisted of folding and unfolding the child like a book. This was done with the infant in the water. While this treatment was being carried out, a funnel, either of glass

or rubber, about three or four inches in diameter, attached by rubber tubing to a tank of oxygen, was held as closely as possible over the child's mouth and nose and the oxygen allowed to flow very freely; in fact, at full force. The irritation to the respiratory tract produced by the oxygen caused rapid respirations and crying. The oxygen was continued and the pallid or livid hue gave way in a few seconds to a bright, rosy color. Occasionally, in extreme cases, he used Laborde's method, rhythmic traction on the tongue eight or ten times a minute. This could be done in connection with Byrd's method and with the funnel still at the mouth. After this the child should be bathed and then laid on the right side with a hot water bag to its back. It was a good plan to make these children cry once an hour for several hours.

Dr. J. O. Polak said that he had been skeptical regarding this method at first, but he had seen a great number of cases resuscitated, and it was amazing to observe the quick change of color. There were many modifications to be made before this method would be perfect.

Spontaneous Intrapartum Rupture of the Uterus Due to Absence of the Vagina.—Dr. Louis J. Ladinski presented this patient and specimen. The patient was twenty-three years of age, and had been married eleven months. She had not menstruated until the age of fifteen, after a specialist had performed some operation upon her, the nature of which she did not know. She was sent to Beth Israel Hospital on March 28, 1910. Physical examination revealed all the signs of a full term pregnancy, with the fetus in the normal position, vertex presentation. About one-half an inch above the introitus vaginæ there was a thick septum, in the center of which was an opening about one-quarter of an inch in diameter. No vagina or cervix could be palpated by rectal examination. The fetal head could be distinctly felt pressing against the septum. He had the patient prepared for a thorough examination under anesthesia the following day, but during the night she began to have labor pains. Before he was able to reach the hospital she suddenly went into collapse, and became cyanotic, with a rapid, uncountable pulse. The fundus uteri could not be felt at all; the epigastrium was bulging, tense, and dull. The fetal contents could be made out right beneath the abdominal wall. Laparotomy was at once performed. The peritoneal cavity was found to be distended with a large amount of free and clotted blood. The body and extremities of the fetus extended through a rent in the anterior wall of the uterus; the head was still grasped by the contracting ring of the lower segment of the uterus and cervix. On withdrawing the fetus the placenta followed. The uterus was low down in the pelvis, hard, and contracted, with a complete transverse rent at the level of the junction of the body and the cervix extending through the entire anterior wall and embracing part of the posterior wall, so that the uterus remained attached to the cervix by only a narrow isthmus. The entire uterus was removed. This was a case in which there was complete absence of the vagina, the cervix uteri extending down to the introitus vaginæ.

Absence of Vagina; Rudimentary Horn of Uterus; Restorative Operation.—Dr. Louis J. Ladinski presented this patient, who was twenty years old, and single. She had never menstruated, but had had menstrual molimina once every four weeks, characterized by cramplike pains in the abdomen. The external genitalia were normal; the introitous vaginæ was represented by a shallow vestibule, in the center of which, and about three-quarters of an inch below the meatus urinarius, was a very small sinus which admitted a probe to a distance of one-half an inch. The perineal body was small, thus making the distance between the urethra and anus shorter than normal. Rectal examination failed to show the presence of a uterine body; the adnexa, however, was palpable. A laparotomy was performed on August 4, 1909, and showed that both tubes and ovaries were present, the latter showing decided signs of ovulation. The uterus was absent, and in its stead were two rudimentary horns, each situated laterally and joined by a broad, thick membrane which extended downward to the junction of the bladder and rectum. The bladder was then carefully separated from the rectum down to the floor of the pelvis, showing both ureters very distinctly. The dissection was carried down to within a few inches of the introitus vaginæ. The space was then packed with iodoform gauze and its upper border closed with a few sutures. After closing the abdomen the patient was placed in the lithotomy position and a transverse incision made into the vestibule. This was deepened by separating the bladder from the rectum by alternating sharp and dull dissection. By using the gauze packing in the upper cavity as a guide a communication was made between the upper and lower channels. The newly formed vagina could now easily admit two fingers to the depth of eight or nine inches. The new vagina was packed with iodoform gauze. On August 17 the granulating cavity was covered with skin grafts. This was not successful. On September 7 skin grafts placed upon sterile silver foil with raw surfaces up was done and results were for the most part satisfactory.

Case of Ruptured Tubal Pregnancy; Death Without Operation.—Dr. Philander A. Harris of Paterson exhibited a specimen consisting of the uterus, tubes, and ovaries removed at autopsy, death having been due to ruptured tubal pregnancy, presumably not advanced beyond two or three weeks of gestation. The growth occurred in the isthmian portion of the left tube, so well in the uterus as to probably constitute a so-called cornual pregnancy. This patient was perfectly well until about four o'clock in the morning, at which time she was seized with very severe colics, and was attended by her physician until she died at eleven o'clock that morning, just seven hours after the first symptoms. She was believed by her physician to be suffering from a criminal abortion, and probably on that account tubal pregnancy was not diagnosticated. The patient denied any history of interference. Dr. Harris was asked to be present at the official autopsy. There were found in the abdominal cavity several quarts of dark blood and many clots. A median line anterior section of the corpus, fundus, and cervix uteri showed the presence of a very considerable decidual formation in the cavity of the uterus, and presented no evidence whatever of intrauterine traumatism. This case was reported by Dr. Harris as an instance of very prompt death from ruptured tubal pregnancy without surgical interference.

A Case of Ovarian Pregnancy.—Dr. George H. Balleray presented a specimen which was removed from a woman forty years old, married ten years, but never pregnant. After skipping her menstrual period two weeks, she had an irregular discharge of blood; then she had an interval of one month with no discharge, and then a recurrence, with intense pain in the lower abdomen. There was abdominal distention and vomiting. After a time operation was performed and a mass was removed, apparently a four-months-old fetus. Outside the mass was made up of ovarian tissue. Dr. Balleray had always maintained that there was no such thing as a true ovarian pregnancy, but from a study of the gross anatomical conditions presented by the specimen he believed it to be a true ovarian pregnancy.

A Case of Interstitial Pregnancy.—Dr. J. O. Polak presented this specimen, which he removed only a few hours before the meeting. The patient was thirty-four years of age, married five years, two children, the last born February 26, 1010. On April 4 she bled for a few days. She was admitted to the hospital, where she remained a few days and then was discharged cured. She

had attacks of pain and intermittent bleeding until April 28, when, at eight o'clock in the morning, she entered into a state of collapse and was brought to the hospital in a state of shock. He removed the uterus. The specimen revealed an interstitial pregnancy. This he intended to present to the pathologist and would make a report at some subsequent meeting of the section.

Ectopic Gestation from the Standpoint of the General Practitioner.—Dr. Guy L. Hunner of Baltimore read this paper. He called attention to the failure to diagnose ectopic gestation when the symptoms were such that the only reason for the failure was that the physician was not on the lookout for this condition. The surgeon was at fault for having taught that the diagnosis could rarely be made before the tragic stage. The general practitioner should, in the majority of cases, make the diagnosis upon the history alone. He cited several atypical cases, but said that these did not at all alter the statement that he had made. With a history of rectal tenesmus, sudden agonizing pain, and collapse, the physician had to make a diagnosis between ureteral calculus, appendicitis, and ectopic pregnancy, a thing not always easy to do. If the case was one of calculus the urine would show blood. Unfortunately, it might also show blood in an appendix case. In ectopic pregnancy with rupture a history could usually be elicited of a missed period and of recent intramenstrual show, and also a history of recent pressure or boring pain. There was present in many cases the evidence of severe internal hemorrhage. The patient should not be disturbed for purposes of examination for fear of stirring up new hemorrhage. As to the advantages of immediate operation on cases in extreme shock from hemorrhage, Dr. Hunner said that he did not like to lay down hard and fast rules for himself or for others. If the patient could be operated upon in good surroundings and was in a condition that promised survival from the operation, he preferred early operation to the risk of further hemorrhages. If a surgeon of wide experience with surroundings that insured rapid and clean operation could not be had he preferred the hibernation treatment. Dr. Hunner reviewed the etiology of ectopic pregnancy and discussed the relation between this condition and appendix diseases. In 34 cases of ectopic pregnancy in his private records the appendix was not mentioned in 13 cases, 5 of these having been vaginal operations. In 3 cases it was considered normal and in 18 diseased. He thought that in the majority of cases of ectopic pregnancy there was a history pointing to appendix disease or well-marked changes of a chronic character in the appendix and its neighborhood. During Dr. Hunner's service at Johns Hopkins Hospital there had been 3,300 patients in the gynecological service, and but 34 cases of pregnancy outside the uterus. Eight of his 34 cases of ectopic gestation were diagnosed before rupture, an unusually large percentage. Six of these eight cases were operated upon in the unruptured state. The only death in his list was from a condition of intestinal paresis and obstruction. With the general practitioner and the surgeon both alive to the possibility of ectopic pregnancy there would certainly occur some unnecessary operations, but it was better to operate upon an occasional patient unnecessarily than to lose a case by hemorrhage. The diagnosis having been made of ectopic pregnancy before rupture, operation should follow at the earliest possible moment. After rupture every effort should be made to keep the patient quiet mentally and physically until conditions could be arranged for a rapid, clean operation. If at a distance from a hospital, the operation should be performed at home. If the patient was transported to a hospital, sufficient time should elapse to demonstrate that she was not bleeding. While waiting for better conditions morphine should be used to quiet the patient.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Oklahoma State Board of Medical Examiners.

April, 1910.

PHYSIOLOGY.

1. What effect has respiration upon the circulation?
2. What is the action of the nervous system upon the salivary glands?
3. What is the function of gastric juice?
4. What is the nervous mechanism of stomach digestion?
5. What are the functions of the liver?
6. What circumstances affect glandular activity?
7. What is a ganglion?
8. What is the effect of stimulation of the divided optic nerve?
9. What is the duty of the large intestine in digestion?
10. What are the uses of the blood?

CHEMISTRY.

1. How may ferric hydrate be hurriedly prepared? When and how should ferric hydrate be used as an antidote?
2. How may lead enter the system and produce lead poisoning? Give a diagnosis of lead poisoning and mention the chemical antidotes for it.
3. Mention the principal products obtained from petroleum and describe the properties of one of the products mentioned.
4. How is chloroform (*a*) prepared, (*b*) tested for impurities?
5. Mention a chemical antidote for sulphuric acid and explain the action of this antidote.
6. How would you detect the presence of bile in the urine?
7. Designate the following as chemical or physical changes: (*a*) The souring of milk; (*b*) decomposition of sunlight by means of prisms; (*c*) converting water into steam; (*d*) dissolving salt in water; (*e*) decay of wood.
8. Technical name of: (*a*) Aqua regia, (*b*) aqua fortis, (*c*) oil of vitriol.
9. Give the formula for: (*a*) Mercuric chloride, (*b*) cupric nitrate, (*c*) calcium carbonate.
10. Give formula for carbolic acid. How is it obtained and what are its properties and uses?

PATHOLOGY AND BACTERIOLOGY.

1. What are some of the phenomena attending pus formation?
2. What are some of the conditions favorable to the increase of bacteria; and what is meant by their toxic products?
3. What is immunity and how produced?
4. Describe the protective agencies by which the body guards itself against the entrance and harmful effects of pathogenic microorganisms.
5. Describe the comma bacillus, and give the manner of its introduction into the system.
6. How should sputum be examined for tubercle bacilli?
7. What is ischemic paralysis?
8. Describe syphilitic gummata.
9. Give the probable causes of occlusion of the bile duct.
10. What are cysts, and how formed?

PHYSICAL DIAGNOSIS.

1. Diagnose mitral regurgitation.
2. Give the physical signs of pericarditis.
3. How would you diagnose aneurysm of the thoracic aorta?
4. Describe the physiological action of the heart.
5. Define rude respiration, bronchial respiration, cavernous respiration, and amphoric respiration.
6. Classify pulmonary tuberculosis. What is the positive diagnostic sign?
7. Describe test for blood in urine.
8. Give physical signs in acute appendicitis.
9. Describe the normal signs of the heart.
10. Give physical signs of acute otitis media.

THEORY AND PRACTICE OF MEDICINE.

1. Write a prescription for (*a*) a collyrium, (*b*) a suppository, and (*c*) a mouth wash.
2. Prescribe a local application for erysipelas, for rhus toxicodendron poisoning; also write a prescription for night sweats of phthisis, for ascites, and for ptyalism.
3. In what disease does leucocytosis occur, and in what diseases is it absent?

4. Give the cause and treatment of bronchial, spasmodic, or essential asthma.
5. Describe the Brand method of treatment in typhoid fever, and what is your opinion of the same?
6. Describe the skin appearance in (*a*) rubeola, (*b*) rubella, (*c*) scarlatina, and (*d*) varicella.
7. Give etiology, symptoms, and treatment of gastrointestinal catarrh of infancy and childhood.
8. Make a differential diagnosis between renal colic and hepatic colic.
9. What are the symptoms of obstruction of the ductus communis choledochus?
10. Differentiate heat exhaustion from sunstroke.

OBSTETRICS AND HYGIENE.

1. Differentiate a foot from a hand presentation. What would you do in either case?
2. What is the bag of waters? What is its function during pregnancy? During labor?
3. How diagnose hour-glass contraction with retained placenta? (*b*) Give treatment.
4. After the fifth month, how may death of fetus *in utero* be recognized; (*b*) what should be done?
5. When and how is the placenta formed?
6. (*a*) State fully the duties of physicians as required by the statutes of Oklahoma. (*b*) What diseases must be reported to the State Commissioner of Health?
7. What are the dangers of cold storage foods?
8. What evil consequence may arise from the use of tobacco?
9. Describe procedure in disinfecting and disposing of typhoid fever stools.
10. (*a*) How much water per day, in ounces, should be consumed by an average adult? (*b*) Mention most frequent pollution of water. (*c*) Give test for organic matter in water.

GYNECOLOGY.

1. Name the most frequent causes of endometritis; (*b*) give treatment, both palliative and surgical.
2. What is atresia of the vagina? Give treatment.
3. Give most frequent causes of pyosalpinx; diagnosis and treatment.
4. Differentiate between menorrhagia, metrorrhagia, and amenorrhea. (*b*) Give treatment of each.
5. Give treatment of prolapsus uteri, both palliative and surgical.
6. Differentiate between ovaritis, cystic ovary, and salpingitis.
7. Give symptoms and treatment of extrauterine pregnancy.
8. Describe the female genital and pelvic organs, and give their functions.

SANITARY SCIENCE.

1. In case you were a health officer, what regulations would you prescribe governing schools, water supply, and sewerage?
2. What would be the most important precautions to be observed for the preservation of health in a city of 20,000 people?

SURGERY.

1. Define hemorrhoids, name varieties, and give treatment.
2. Give differential diagnosis between osteomyelitis and acute rheumatism, and describe treatment of former.
3. Give technique of tracheotomy.
4. Diagnosis and treatment of strangulated inguinal hernia.
5. Give your rule for locating and method of ligating the femoral artery *in situ*.
6. Diagnose and give treatment of dislocation of the astragalus.
7. Name and describe the measurements you would use in ascertaining whether or not there is shortening in neck of femur in case of suspected impacted fracture.
8. What would be your treatment of compound fracture of tibia with laceration of the anterior tibial artery?
9. Differentiate floating kidney from other abdominal tumors, and describe treatment for same.
10. Give diagnosis and treatment of intussusception.

MEDICAL JURISPRUDENCE.

1. What conditions would you find in a case of rape of a girl of twelve years?
2. Enumerate the causes of sudden death.
3. Give the difference between an incised wound made before and one made after death; also gunshot wound.
4. Give the cause and duration of rigor mortis.
5. To what kind of a crime does strangulation point; also hanging?

TOXICOLOGY.

1. What is the antidote and treatment of oxalic acid poisoning?
2. Give the detailed account of post-mortem appearance of carbolic acid poisoning.
3. What are the symptoms and treatment of poisoning with bichloride of mercury?
4. What is the antidote for strychnine?
5. Mention ten drugs, the use of any one of which may cause skin eruptions.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

OKLAHOMA STATE BOARD OF MEDICAL EXAMINERS.

April, 1910.

PHYSIOLOGY.

1. The respiratory changes in the blood: (1) In the *lungs* the blood is changed in color, gains oxygen, loses carbon dioxide, loses heat, and loses watery vapor. (2) In the *capillaries of the body* the blood loses oxygen and receives carbon dioxide.
2. The submaxillary gland is supplied by the chorda tympani (which contains secretory fibers and vasodilator fibers). The sympathetic slows the secretion of saliva in parotid and submaxillary glands. In the parotid gland the auriculotemporal is the secretory nerve. The secretion of saliva is a *reflex* action; the *afferent* nerves being: The glossopharyngeal, the lingual branch of the fifth, and the chorda tympani; the *efferent* nerves are: Sympathetic nerves, auriculotemporal branch of the fifth, and chorda tympani.
3. The *function of gastric juice* is: (1) To change proteids into proteoses and peptones; (2) to curdle the casein of milk; (3) it is also antiseptic.
4. The pneumogastric nerves are *motor* to the stomach, and induce peristalsis; the sympathetic fibers are inhibitory, causing cessation of peristalsis and dilatation of the sphincter pylori.
5. The functions of the *liver* are: (1) The secretion of bile, (2) the formation of glycogen, (3) the formation of urea and uric acid, (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.
6. *Circumstances affecting glandular activity* are: Blood supply; nerve impulses (trophic, secretory, vasomotor); sometimes food, sensations, or emotions.
7. A *ganglion* is an aggregation of nerve cells, connected with nerves, or other ganglia, or with the cerebrospinal axis; masses of gray matter at the base or in the interior of the brain are also called ganglia.
8. Stimulation of the divided optic nerve causes: Flashes of light, but no pain.
9. *In the large intestine:* Digestion which is already begun may continue, but there is no special digestive action; there is marked absorption of water; there are numerous bacteria, and, as a consequence, proteid putrefaction.
10. The *functions of the blood as a whole* are: To distribute nourishment, oxygen, and the internal secretions to the tissues of the body; to remove carbon dioxide and other waste matters from the tissues so that they may be excreted by the lungs, kidneys, and skin; to regulate the body temperature. In addition the *white corpuscles* serve as a protection to the body from the incursions of pathogenic microorganisms: they take some part in the process of the coagulation of the blood; they aid in the absorption of fats and peptones from the intestine, and they help to maintain the proper proteid content of the blood plasma.

CHEMISTRY.

1. Ferric hydrate may be hurriedly prepared by precipitating solution of ferric sulphate with magnesia. The two solutions should be kept in separate bottles, and when needed they may be mixed and administered. It is used as an antidote in acute arsenical poisoning.
2. The most *common sources of lead poisoning* are the following: "The contamination of drinking water from lead pipes. Contamination of articles of food or drugs by contact with leaden vessels, or from being enclosed in tinfoil containing an excess of lead. Drinking beer, cider, etc., which has been drawn through leaden pipes or allowed to stand in pewter vessels. The ingestion or constant handling of lead or its compounds, as the acetate, nitrate, carbonate (white lead—painter's colic), Goulard's extract, etc. The use of hair dyes containing lead."

Lead poisoning causes: Metallic taste, dryness of throat, thirst, severe, colicky abdominal pains, particularly in um-

bilical region; pulse feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of lower extremities; convulsions; tetanic spasms, and (in chronic cases) wrist drop. *Chemical antidote* is magnesium sulphate.

3. Principal products of petroleum are: Paraffin, vaseline, kerosene, benzine, gasoline, mineral oils, rhigolene. *Vaseline* is a yellowish or whitish fatty substance, with slight odor and taste, and is sticky.

4. Chloroform is prepared by the action of calcium hypochlorite on acetone. It is *tested:* (1) For excess of alcohol, by taking the specific gravity; (2) for HCl and Cl, by shaking it with water, which afterward should not give a precipitate with $AgNO_3$.

5. Chemical antidote for sulphuric acid is magnesia; it acts by neutralizing the acid and converting it into a harmless salt.

6. *Test for bile pigment in the urine:* Put 3 c.c. HNO_3 in a test-tube; add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquid, which gradually rises, and is succeeded from below by blue, reddish violet, and yellow.

7. (*a*) Chemical; (*b*) physical; (*c*) physical; (*d*) chemical; (*e*) chemical.

8. (*a*) Aqua regia is nitrohydrochloric acid; (*b*) aqua fortis is nitric acid; (*c*) oil of vitriol is sulphuric acid.

9. (*a*) Mercuric chloride, $HgCl_2$; (*b*) cupric nitrate, $Cu(NO_3)_2$; (*c*) calcium carbonate, $CaCO_3$.

10. Carbolic acid, C_6H_5OH. It is obtained by heating phenyl iodide and potassium hydroxide. It is a crystalline substance, with characteristic odor and acrid, burning taste, neutral in reaction, and very soluble in alcohol and ether. It is used as an antiseptic and in the manufacture of medicinal compounds, dyes, and explosives; also as a local anesthetic, for pruritus, and sometimes internally in nervous vomiting.

PATHOLOGY AND BACTERIOLOGY.

1. See Da Costa's "Surgery" (1908), pages 127, 130, and 132.

2. Most bacteria require (1) proper temperature, generally at or near that of the body; (2) oxygen is generally needed, those that cannot live without it being called aerobic, and those that can grow without it, anaerobic; nutriment of a proper kind, containing both organic and inorganic material; a slight degree of moisture: a medium of slightly alkaline reaction, and rest. Individual bacteria may require modifications of the above essentials.

By the toxic products of bacteria is meant the production of disease or infection by bacteria.

3. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic bacteria. Immunity may be either natural or acquired.

Natural immunity is this power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired: (1) By a previous attack of the disease caused by the bacteria, or (2) by the person being made artificially insusceptible. The conditions which give immunity from the pathogenic action of bacteria are: (1) A previous attack of the disease; (2) inoculation with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Several theories have been advanced to account for immunity, but the only two that are considered now are: (1) Metchnikoff's theory of phagocytosis and (2) Ehrlich's side-chain theory. This latter "is based on the idea that the toxin destroys a cell by entering into chemical union with it. The molecule of toxin contains at least two groups of atoms, a *toxophore* group, in which the poisonous principle resides, and a *haptophore* group, which brings the toxophore group into touch with the cell and through which chemical combination takes place. Similarly, the cell contains a haptophore group, but the toxophore group of the toxin can only unite with it and destroy it when its haptophore companion has affinity with that of the cell. If that affinity does not exist the two haptophore groups do not unite, the toxophore group does not come into contact with the cell, and the animal is immune. Such is natural immunity. If there is affinity and the cell can throw off a haptophore group (antitoxin), which in its detached condition unites with the haptophore group of the toxin, the toxophore group has then nothing with which it can unite and the animal is immunized. When the individual has to contend with a bacterium as well as its toxin, the same principle obtains. Immunity is established by the production of a double haptophore group, one for the bacterium, the other for its toxin."—(Stenhouse's *Pathology.)*

4. The chief protective agencies by which the body guards itself against the entrance and harmful effects of pathogenic microorganisms are: The acidity of the gastric juice, urine, and the vaginal secretion; the alkalinity of the blood; the agglutinating action of the blood; the bactericidal action of the blood and lymph; the action of leucocytes and phagocytes; the general antitoxic action of the organism.

5. The *comma bacillus* is a spirillum, actively motile, and with a flagellum at one end; it is curved, has rounded ends, and is about half the length of the tubercle bacillus; it stains readily with ordinary anilin stains, but not by Gram's method; it is easily cultivated on the usual media; it has but slight power of resistance; it liquefies gelatin, and does not produce pigment.

It may be introduced into the system by: water, milk, food, fingers, and flies.

6. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

7. *Ischemic paralysis* is a local paralysis due to stoppage of the circulation in a part (often the result of embolism or thrombosis). It is also another name for myositis fibrosa, or fibrous degeneration of muscles.

8. *Syphilitic gummata* are firm, elastic, yellow or whitish nodular masses, varying in size from a tubercle to an orange. Their shape and outline are irregular, owing to fibrous processes which go through them; they often have a kind of capsule consisting of fibrous-looking but translucent material, which fastens them firmly to adjacent structures. On section they are mucoid or gelatinous, and vascular. *Microscopically,* they consist of round cells and giant cells, nuclei, fat granules and cholesterin; around this portion will be found epithelioid cells, and an outer layer consisting of leucocytes, giant cells, and epithelioid cells. There is some intercellular material; and blood-vessels are present.

9. *Occlusion of the bile duct* may be due to: Foreign bodies within the duct (gallstones, hydatids, or other parasites, inspissated bile); thickening of the mucosa due to inflammation, or cicatricial overgrowth of connective tissue; pressure from without (tumors, enlarged glands, aneurysm); adhesions, due to peritonitis.

10. A *cyst* is a circumscribed cavity containing liquid or pultaceous material. Cysts may be *formed:* (1) By the accumulation of secretions and other products within cavities which are already in existence; and (2) independently, by the softening or liquefaction of tissues.

Varieties: Retention cysts, dilatation cysts, exudation cysts, extravasation cysts, parasitic cysts, congenital cysts, dermoid cysts.

PHYSICAL DIAGNOSIS.

1. See French's "Practice of Medicine" (1907), page 579; or Osler's "Practice of Medicine" (1909), page 807.

2. See French's "Practice of Medicine" (1907), page 560; or Osler's "Practice of Medicine" (1909), pages 777 and 779.

3. See French's "Practice of Medicine" (1907), pages 630 to 633; or Osler's "Practice of Medicine" (1909), pages 857 to 861.

4. A *complete physiological revolution of the heart* or *cardiac cycle* includes all the changes which occur between the commencement of one heart-beat and the commencement of the next; it consists of the alternate contractions (or systole) and relaxations (or diastole) of the auricles and ventricles of the heart. The contraction of the two auricles takes place simultaneously and is followed by the simultaneous contraction of the two ventricles; then follows a period during which the whole heart is in a state of diastole. The cycle then begins again with the auricular systole.

5. *Rude Respiration* is a form of breathing which is neither bronchial nor vesicular, but partakes of the characteristics of both; it is generally called bronchovesicular breathing.

Bronchial Respiration is characterized by absence of the vesicular quality. Inspiration is high pitched and tubular;

expiration is higher pitched and prolonged; the two are separated by a short interval.

Cavernous Respiration is a blowing sound, but constant, heard during both inspiration and expiration, lower in pitch than bronchial respiration, and hollow in character.

Amphoric Respiration is a blowing respiration, of metallic or musical quality; it is present in inspiration and expiration.

6. Pulmonary tuberculosis is classified as an infectious disease. The positive diagnostic sign is the finding of the tubercle bacilli in the sputum. See above, PATHOLOGY, Question 6.

7. Test for *Blood.*—To the urine add a solution of potassium hydroxide to distinct alkaline reaction; heat nearly to boiling (do not boil). A red precipitate is produced.

8. See French's "Practice of Medicine" (1907), page 792; or Osler's "Practice of Medicine" (1909), page 514.

9.

10. See Rose and Carless' "Surgery" (1908), page 882.

THEORY AND PRACTICE OF MEDICINE

1. (*a*) *A Collyrium*:

℞ Atropinæ sulphatis, gr. ij.
Sodii chloridi, ʒr. ij.
Aquæ destillatæ, ʒss. Misce.

Signa: One drop to be placed in the eye every night.

(*b*) *A Suppository*:

℞ Cocainæ hydrochloridi, gr. ij.
Aquæ destillatæ, ♏ vj.
Olei theobromatis, ʒjss. Misce.
Fiant suppositoria No. vj.

Signa: Insert one night and morning.

(*c*) *A Mouth Wash*:

℞ Thymol, gr. vij.
Spiritus chloroformi, ʒvj.
Spiritus menthæ piperitæ, ʒij.
Tincturæ hamamelidis q.s. ad ʒiv. Misce.

Signa: One teaspoonful to be added to two tablespoonfuls of water, and used after each meal.

2. *For Erysipelas*:

℞ Ichthyol, ʒss
Olei citronellæ, ♏xx.
Adipis, ʒj. M.

Signa: Apply as directed.

For Rhus Toxicodendron Poisoning:

℞ Fluidextracti grindeliæ robustæ, ʒj.
Aquæ, ʒx. M.

Signa: Apply as directed.

For Night Sweats of Phthisis:

℞ Acidi camphorici, ʒiv.
Alcohol, ʒij.
Mucilaginis acaciæ, ʒiij.
Syrupi aurantii corticis, q.s. ad ʒvj. M

Signa: One dessertspoonful one hour before sweat is expected.

For Ascites:

℞ Pulveris digitalis.
Pulveris scillæ, āā Gr. xx. M.
Fiat massa in pilulas No. xx. dividenda.

Signa: One every five hours.

For Ptyalism:

℞ Atropinæ sulphatis, gr. ss.
Sacchari lactis, ʒj. M.
Ft. in caps. No. L.

Signa: One after each meal.

3. *Leucocytosis* occurs in: Cholera, relapsing fever, typhus, scarlet fever, diphtheria, tonsillitis, syphilis, erysipelas, bubonic plague, pneumonia, smallpox, malignant endocarditis, septicemic conditions, actinomycosis, glanders, rheumatism, meningitis, affections of gall-bladder, pancreatitis, endometritis, gonorrhea, abscesses, carbuncle, furuncle, appendicitis, pyonephrosis osteomyelitis salpingitis, inflammations of serous membranes, many inflammatory skin diseases, and in many cases of poisonings.

Leucocytosis is absent in: Typhoid, malaria, influenza, measles, rötheln, and tuberculosis. (From Cabot's *Examination of the Blood.*)

4. See French's "Practice of Medicine" (1907), pages 658 and 661; or Osler's "Practice of Medicine" (1909), pages 609 and 612.

5. See French's "Practice of Medicine" (1907), page 113; or Osler's "Practice of Medicine" (1909), page 100.

6. (*a*) *Rubeola*: Character of eruption, small, dark red papules with crescentic borders, beginning on face and rapidly spreading over the entire body; desquamation is branny. The eruption is dark, not uniform, shotty.

(*b*) *Rubella*: The rash is more diffuse, and is of a rose-red color, is brighter, and less crescentic than in measles. It appears on first day, is most intense on second day, consists of red papules, often fades from face before it is seen on the limbs.

(*c*) *Scarlatina*: A scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform.

(*d*) *Varicella*: The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured.

7. See French's "Practice of Medicine" (1907), page 782; or Osler's "Practice of Medicine" (1909), page 507.

8. In *renal colic:* The pain is in the region of the affected kidney; it radiates down the thigh; there are intense rigors; retraction of the testicle may be present; also history of previous attacks or of calculi; the urine may be scanty, suppressed, or bloody.

In *hepatic colic:* The pain is in the region of the liver; it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; calculi are found, if at all, in the feces.

9. See Osler's "Practice of Medicine" (1909), page 547.

10. See French's "Practice of Medicine" (1907), page 969; or Osler's "Practice of Medicine" (1909), page 385.

OBSTETRICS AND HYGIENE.

1.

FOOT.	HAND.
This is at right angles to the leg.	This is a straight line with the arm.
The inner border is thicker than the outer.	Both borders are of equal thickness.
The toes are short and are in a straight line.	The fingers are longer, and the thumb is at right angles to the other digits.
The great toe cannot be altered in its relation to the remaining toes.	The thumb may be bent across the palm, and thus brought into contact with the other fingers.
The toes cannot be separated to any great extent.	The thumb and first finger may be considerably separated.
The malleoli and heel (projecting os calcis) may be felt.	There is an absence of such features.
The ankle-joint is not freely movable.	The wrist joint is quite movable.

—(Dorland's *Obstetrics.*)

For treatment, see Williams' "Obstetrics" (1909), page 802.

2. The bag of water is the amniotic sac with the liquor amnii; this latter is alkaline in reaction, has a specific gravity of about 1.001 to 1.008, its quantity is variable, but is generally about two pints. It consists chiefly of water, but contains small amounts of albumin, epithelial cells, urea, phosphates, chlorides, etc. Its source is unsettled.

Functions.—(*a*) *During pregnancy:* (1) As a protection to the fetus against pressure and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus, and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus.

(*b*) *During labor:* It acts as a fluid wedge, and dilates the os uteri and the cervix; it also slightly lubricates the parts.

3. See Williams' "Obstetrics" (1909), page 664.

4. *Symptoms* of death of the fetus during the later months of pregnancy are: Cessation of the signs of pregnancy, the abdomen and uterus are both diminished in size, the fetal heart sounds and movements cease, there is no pulsation in the cord, the mother's breasts become flaccid and occasionally secrete milk. If the fetus has been dead for some time, crepitus of its cranial bones may be elicited. *Treatment:* Abortion or premature labor must be induced, and the contents of the uterus removed immediately.

5. See Williams' "Obstetrics" (1909), page 128; or Hirst's "Obstetrics" (1909), page 120.

6. (*a*) To report all cases of infectious and contagious diseases; to effect a temporary quarantine on these same cases; to report all births and deaths occurring in their practice. (*b*) All infectious and contagious diseases.

7. *The dangers of cold-storage foods* are: The keep-

ing quality of the food is impaired, and so the food must be consumed soon after it leaves the cold storage; danger may lurk in the ice, particularly when not made from pure water; a similar danger exists when food is put in dirty water and surrounded by ice; ptomaine poisoning may occur; typhoid bacilli may retain their vitality even in water at the freezing point.

8. "The continued use of tobacco, by smoking or chewing it to excess, produces granular inflammation of the fauces and pharynx, atrophy of the retina, dyspepsia, lowered sexual power, sudden faints, nervous depression, cardiac irritability, and occasionally angina pectoris. Used by the young, it hinders the development of the higher nerve centers and impairs the nutrition of the body by interfering with processes of digestion and assimilation. It has been credited with causing cancer of the lips and tongue, blunting the moral sense, mental aberration, and even insanity."—(Potters' *Materia Medica.*)

9. See French's "Practice of Medicine" (1907), page 108; or Osler's "Practice of Medicine" (1909), page 97.

10. (*a*) About 65 to 70 ounces of water should be drunk in a day, besides about 20 ounces taken in as an ingredient of solid food. (*b*) *The chief sources of contamination of drinking water* are: Sewage, including not only solid and liquid excreta, but also house water and waste water; manufacturing refuse, such as from dye works, bleaching works, tanneries, and numerous other industrial places; from improper storage or service of water. (*c*) The presence of organic matter is shown by the change of color which occurs in a pink solution of potassium permanganate; it loses oxygen and becomes brownish.

GYNECOLOGY.

1. *Endometritis:* The acute form is due to the introduction of septic bacteria, and is manifested by pain, constipation, irritability of bladder, rapid pulse, rise of temperature, and a profuse discharge. *Treatment* following miscarriage or labor consists in curettage, intrauterine hot sterile douche, free purgation, hot over the lower abdomen, milk diet, and stimulants. Chronic endometritis may accompany numerous pathological uterine conditions, but is generally due to gonorrhea. The symptoms are backache, headache, leucorrhea, profuse menstruation, and impairment of the general health. *Treatment* consists in removing the cause when possible, and when due to gonorrhea curettage and irrigation of the uterus, with the application of an antiseptic.

2. Atresia of the vagina is an obstruction of the vagina by adhesion (either congenital or acquired). *Treatment:* Adhesions are to be separated, bands cut off short, cicatricial tissue dissected out, the wound closed, and a dilator inserted into the vagina.

3. *Most frequent causes of pyosalpinx* are: Gonorrhea, puerperal septic endometritis, and sepsis from use of dirty instruments. It is *diagnosed* by: Pain or discomfort, made worse by pressure, examination, or defecation; or colicky pains over the tube; dysmenorrhea; increased menstrual flow; tubes are found to be dilated and swollen *Treatment:* Removal of the affected tube.

4. *Menorrhagia* is an excessive loss of blood at the menstrual periods. *Metrorrhagia* is a hemorrhage from the uterus at other than the menstrual periods. It is very often impossible to differentiate the two conditions. *Treatment:* Remove the cause, if possible; treat abnormal conditions that are present; vaginal douches, tampons, and curettage have been recommended; also ergot, hamamelis, hydrastis, and viburnum prunifolium: rest in bed is necessary. Intrauterine applications of astringents or of adrenalin have been used. *Amenorrhea* is absence of menstruation during the period of sexual activity. *Treatment* consists in: (1) Removing the cause, if possible; (2) general treatment by means of proper hygiene, rest, diet, bathing, attention to the bowels, exercise, etc.; (3) drugs reputed to be emmenagogues such as iron, manganese, aloes, strychnine, apiol, oxalic acid, savine, rue, and tansy.

5. PROLAPSUS UTERI. *Treatment:* "Operative, unless some contraindication to operation exists. In such a case some *mechanical device* should be tried for the support of the uterus. Pessaries are not to be recommended, as their constant use leads to irritation and excoriation of the vaginal walls. Probably the best means for supporting the uterus is by Braun's colpeurynter. This is worn only during the day, and can be introduced by the patient herself every morning. The uterus is replaced and the colpeurynter well anointed with carbolized vaseline and containing about an ounce of water, is introduced into the vagina. It is then distended with air, thus making an even pressure on the vaginal walls and not causing ulcerations. *Operative treatment* gives the most satisfactory results in prolapse. In slight cases of prolapse repair of the perineum will effect a cure. The severer grades will require, in addition, some operation on the anterior vagina. The best of these is Martin's operation for cystocele. If the cervix is hypertrophied it should be amputated. Three operations—on the perineum, for cystocele, and amputation of the cervix—are required in the usual case of prolapse. In addition, hystrorrhaphy may be advisable, since there can be no prolapse so long as the uterus maintains its normal position of anteflexion. These operations failing, hysterectomy may be performed."

6. In *ovaritis:* The ovary is increased in size; is tender on pressure, and pressure causes a sickening sensation; is generally displaced (backward); dyspareunia and hysteria may be present. In *cystic ovary:* The condition is generally unilateral, not often adherent, may grow to be very large size. In *salpingitis;* Both tubes are apt to be affected, the tube is oblong and generally adherent, ovary may be palpated as distinct from the tumor usually it is not very large, and there may be leucocytosis.

7. See Williams' "Obstetrics" (1909), pages 644 and 649; or Hirst's "Obstetrics" (1909), pages 303 and 306.

8. See Williams' "Obstetrics" (1909), page 26; or Hirst's "Obstetrics" (1909), page 43.

SANITARY SCIENCE.

1. *Concerning schools:* The school building should be as near as possible to the center of the area which it is to serve; the site should be airy and open, of sufficient size, free from swamps, and somewhat elevated; it should not be too near factories, busy streets, or railways; the soil should be as free as possible from organic matter. The building should be so planned that the corners look towards the four points of the compass. In this way the sun will have access to each side and to every room during some part of the day. The building should have as few stories as possible. The walls should be of brick or stone, and should be pointed with cement; the inner surface of the wall should be cemented smooth. The foundations must be solid. The general arrangement will depend upon size of site, number of scholars, and number of required rooms. Fifteen square feet per child should be allowed. Details will have to be considered on: plans, accommodations to be provided, shape and size of class rooms, distribution of rooms, teachers' rooms, corridors, entrances and staircases, playground, ventilation, heating, lighting, and placing of windows, sanitation, lavatories water supply, drinking water, sewage disposal, removal of refuse, sanitary appliances, and drainage. Special care must be given to the prevention of contagious diseases, and the exclusion of all possible sources of infection or contagion; there should be physical examination of children, also, for non-contagious physical defects.

Concerning water supply: This must be free from excreta of human beings and animals; and the intake must be a sufficient distance from any possible source of pollution by sewage or other impurities. If the water comes from a source which cannot be controlled by inspection, sand filtration or other means of purification must be used.

Concerning sewerage: This should not be deposited into water which may be the source of supply for any town. For small towns, sedimentation and filtration (or some other recognized method) should be adopted.

2. The main thing is the prevention and check of contagious diseases by isolation, quarantine, and subsequent disinfection. There must be a sufficiency of water, and adequate inspection of the source of its supply; examination of food supplies, particularly milk, and insistence that food is not exposed to dust, flies, or other deleterious influences; purity and wholesomeness of milk and water; proper sewage disposal; adequate medical school inspection; proper laboratory facilities for production of antitoxins and vaccines, and for early diagnosis of diphtheria, tuberculosis, typhoid, and malaria; abatement of nuisances (such as noise, smoke, odors).

SURGERY.

1. See Rose and Carless' "Surgery" (1908), page 1148; or Da Costa's "Surgery" (1908), page 1012.

2. In *osteomyelitis:* There are sudden onset, pain, chills, fever, tenderness, swelling of soft parts, sometimes the joint can be moved gently without pain; septicemia or pyemia may be present. In *rheumatism* there is successive involvement of many joints; the tenderness, pain, and swelling are over the joints, and not over the bones; profuse sweats are present, and the condition responds to treatment by salicylates.

In *osteomyelitis* the *treatment* consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece

of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

3. See Rose and Carless' "Surgery" (1908), page 915; or Da Costa's "Surgery" (1908, page 769.

4. See Rose and Carless' "Surgery" (1908), pages 1099 and 1103; or Da Costa's "Surgery" (1908), page 992.

5. See Rose and Carless' "Surgery" (1908), page 340; or Da Costa's "Surgery" (1908), page 423.

6. See Rose and Carless' "Surgery" (1908), page 638; or Da Costa's "Surgery" (1908), page 609.

7. See Rose and Carless' "Surgery" (1908), page 538; or Da Costa's "Surgery" (1908), page 515.

8. See Rose and Carless' "Surgery" (1908), pages 534 and 481; or Da Costa's "Surgery" (1908), pages 540 and 464.

9. See Rose and Carless' "Surgery" (1908), page 1161; or Da Costa's "Surgery" (1908), page 1104.

10. See Rose and Carless' "Surgery" (1908), page 1121; or Da Costa's "Surgery" (1908), pages 838 and 962.

MEDICAL JURISPRUDENCE.

1. In case of rape of a girl of twelve years old, one might find: (1) Marks of violence about the genitals; (2) wounds, bruises, or other marks of injury on the body; (3) bloodstains and seminal stains on the person or clothing.

2. The *causes of sudden death* are: Cerebral hemorrhage; rupture of a gastric ulcer; valvular disease of the heart, especially aortic; angina pectoris; rupture of an aortic aneurysm; suffocation during an epileptic fit; shocks of electricity; sunstroke; mental or physical shock; diabetic coma; uremia; exertion on an overloaded stomach.

3. A wound inflicted during life is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges, and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus, or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization.

4. Rigor mortis is supposed to be due to the coagulation of the myosin in the muscles. It lasts for a variable period, generally from about sixteen to twenty-four hours.

5. *Strangulation* generally points to homicide; *hanging*, to suicide.

TOXICOLOGY.

1. *Antidote* (for oxalic acid) is calcium carbonate, or hydroxide, or magnesia. *Treatment:* Give bland mucilaginous drinks, and antidotes; do not use stomach pump.

2. *Post-mortem appearances in carbolic acid poisoning:* "The mouth and throat show corrosive effects. The mucous membrane is generally white or gray and pultaceous, or it may be hardened and corrugated. The stomach usually shows relatively little corrosion. The blood is dark and fluid. All the fluids of the body exhale the odor of phenol. The bladder is empty, or contains a small quantity of dark or greenish urine. As death is usually due to asphyxia, the veins of the head and brain are congested. Putrefaction is apt to be retarded."—(Riley's *Toxicology.*)

3. *Symptoms* of poisoning by corrosive sublimate are: A burning pain in the mouth, pharynx, and stomach; the mouth and tongue are white; the vomitus is white, with shreds of mucous membrane, and tinged with blood; there may be bloody stools, also salivation. *Treatment:* The antidote is white of egg, but too much must not be given at one time; this should be followed by an emetic.

4. The antidote for strychnine is tannic acid, or weak solution of potassium permanganate.

5. Quinine, cubebs, copaiba, belladonna, bromides, iodides, mercury, salicylic acid, arsenic, and onium.

Helminthiasis in Children.—Schloss has made a routine examination of the stools of a large number of children in New York City for intestinal parasites. Twelve of 30 children who suffered from unexplained nervous or gastrointestinal symptoms were found to harbor worms. Consecutive examination of 280 children showed 80 to be infected with worms. Thirty-one harbored *Trichiuris trichiura;* 23, *Oxyuris vermicularis;* 20, *Hymenolepsis nana;* 6, *Ascaris lumbricoides,* and 5, *Tenia saginata.* Only one of 33 infected with *Trichiuris trichiura* suffered from symptoms. Thirty-five of the 51 infected with other parasites suffered from symptoms. The eosinophile cells were not increased in the cases of *Trichiuris trichiura.* In infection with other parasites eosinophilia was usually absent when there were no symptoms of helminthiasis and present in cases showing such symptoms.—*The American Journal of the Medical Sciences.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of June 25, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	518	137
Diphtheria	323	37
Measles	843	20
Scarlet Fever	360	20
Smallpox	—	—
Varicella	232	—
Typhoid Fever	26	7
Whooping Cough	60	3
Cerebrospinal Meningitis	4	5
Malarial Fever	—	—
Totals	2,366	229

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended June 24, 1910.

		CASES.	DEATHS.
CHOLERA			
Ceylon, Colombia	April 28	..	..
One case from S. S. Nubia from Calcutta.			
China, Swatow	May 10–16	Present.	
India, Bombay	May 10–17	..	1
Calcutta	April 24–30	..	65
Rangoon	May 1–7	..	1
Java, Batavia	May 1–7	7	4
Samarang	April 17–May 7	143	116
Soerabaya	April 17–May 7	68	34
Philippine Islands, Manila	April 17–23	1	1

PROGRESS IN MEDICAL EDUCATION.

By JACOB GOULD SCHURMAN, D.Sc., LL.D.,
ITHACA, N. Y.
PRESIDENT OF CORNELL UNIVERSITY.

There is much to deplore in the condition of medical education in the United States. With the large number of our proprietary and commercial institutions the number of our medical schools is greater than all the rest of the civilized world put together. The character of the schools may be judged by the fact that nearly half of them have incomes below $10,000. And the valuable and reliable report on "Medical Education in the United States and Canada," published by the Carnegie Foundation, shows that in both countries there are only twenty-three medical schools having a total annual income of more than $50,000; and of these only six have a total annual income of over $100,000; and of these six only three have an annual income of over $200,000, while of these three the medical schools of Cornell University and Harvard University alone have an income of over $240,000. These financial returns are a fair exhibit of the standing of American medical schools, and they demonstrate in a very impressive way the fact that a great number of our medical schools are disgraceful, the majority of them inferior, and only a very small number of them first-class institutions. Good medical education is tremendously expensive; it takes a very large budget to provide salaries for the professors and facilities for teaching and research laboratories, dispensaries, and hospitals.

There are four stages of medical education represented in the great array of institutions which have been so thoroughly investigated by the experts of the Carnegie foundation. And we may regard them as representing four stages in the development of the ideal medical school.

The first stage is that of the apprenticeship, which does not, of course, call for an organized school. In this stage the relation between the master and the pupil is similar in all respects to that between the mechanic and his apprentice. This, I say, was the earliest stage of medical education, and it had at least one great advantage. It brought the pupil into direct contact with the objects of his study, namely, the patients themselves. This advantage was forfeited in the next following stage of medical education.

This is the stage of didactic lectures with quizzes to ascertain if the student has assimilated them. Undoubtedly this second stage of medical education had some advantages over the first. Its fatal defect was the substitution of books and charts and lectures and recitations for actual contact with sick and suffering men, women, and children, whom the student was being trained to heal.

The third stage in the evolution of medical education introduces the laboratory. Medical knowledge was no longer gathered up in packages and transferred in the course of a year by daily doses to students in lectures; but the students were required to ascertain the facts for themselves in the laboratories by the actual study of organs and functions. Of course, the knowledge which the student acquired was already in existence—it was known to his professors and friends. But the laboratory method familiarized the student with the process by which new knowledge is acquired. It made him acquainted with scientific methods. It compelled him to take the attitude of the investigator, and he inevitably learned the technique of the sciences. In a single word, this advance in medical education had two enormous advantages. First, it brought the student into actual contact with the phenomena of his profession, and secondly, it stimulated him to mental activity and creation in place of mere passive assimilation and memory work.

The fourth stage of medical education is only just coming into existence in this country. It is the recognition of the hospital as the supreme laboratory of the medical school. To a certain extent this principle has been adopted by all medical schools which have dispensaries for the treatment of milder forms of disease. But a practising physician has to deal not only with diseases in a mild form, but with diseases in severe and alarming forms. These are the cases, however, which fill hospitals. The final stage in the evolution of the conception of medical education recognizes the hospital, therefore, as an indispensable adjunct to medical education. And if the hospital is to be effectively used, the members of the faculty of the medical school must have the same freedom and right of control in regard to it which they possess in connection with their laboratories in the medical school.

No first-class medical school in the United States to-day possesses such a hospital of its own. The Johns Hopkins Hospital, though a separate organization, has, however, formed an alliance with the medical department of Johns Hopkins University. And this medical department with a total annual income of $102,429 has been greatly strengthened by this reinforcement of hospital facilities. The greatest need of our first-class medical schools to-day is the free and unhampered use of hospitals which they own, or absolutely control on the medical and educational side. I have said that Cornell and Harvard are the only two medical schools in the United States which had an annual budget of over $240,000, and neither Cornell nor Harvard owns a hospital of its own or absolutely controls an outside hospital. The only way in which these schools can utilize hospitals is by appointing to their faculties

*An address delivered at the commencement exercises of the Cornell University Medical School, in New York City, June 15, 1910.

ties gentlemen who are already members of hospital staffs. But this fatally limits the choice of authorities of the university in selecting professors for their medical school. In every other professional school of Cornell University we select the best men we can find in the United States or in the world to fill vacancies. But in the case of our medical school we are limited, not merely to the State of New York, but to the City of New York, and not merely to the City of New York, but to the comparatively small number of physicians and surgeons who are already on hospital staffs in the City of New York. It is perfectly astonishing that with all these limitations we have by the exercise of extraordinary care been able to secure such able and well-trained men. But we cannot count on such lucky accidents permanently. The system is altogether vicious. It is impossible that a medical school should reach the highest stage of development on this basis. As a condition of that goal we must either own or control a hospital of our own.

In the old world it is universally recognized that a hospital, which is an institution for the care and healing of the sick, gets as much advantage by having the members of a medical faculty for its staff as the medical college gets by using a hospital as a place of educational research. Indeed, I do not believe I am going beyond the facts when I say it is universally recognized that the preponderating advantage is on the side of the hospital, for the hospital gets in this way as members of its staff the ablest and best trained physicians and surgeons in the country. In Great Britain, in Germany, in France, and in Austria it would be regarded, not only as an anomaly, but as a piece of barbarism if hospital staffs were closed to university professors of medicine, or if men could not be appointed university professors in medicine unless they had previously, on one ground or another, been appointed members of a hospital staff. That, however, is the condition in New York City, and not only in New York City, but generally throughout the United States. Consequently, this great City of New York, one of the largest and richest cities in the world, stands, both in the matter of medical education and medical research, far behind similar cities in the Old World. The way to establish medical education and medical research on a high plane in this city is for the best hospitals to offer positions on their staffs to the professors in our best medical schools. Considering that the City of New York has poor medical schools as well as good ones, a hospital would be perfectly justified in stipulating that a medical school with which it would affiliate itself must have an endowment of a certain minimum figure, a faculty of a certain size and standing, and students who not only pursued a thoroughly scientific course in medicine, but who were also thoroughly prepared by previous training for entrance upon that medical course. If the Roosevelt, New York, St. Luke's, the Presbyterian, and Mount Sinai hospitals would adopt such a policy they would, in a short time, win a place in medical education and research that would rank them with Guy's and St. Bartholomew's in London, the Royal Infirmary of Edinburgh, the Charité of Berlin, the Hotel Dieu of Paris—and that, too, without sacrificing—but, on the contrary, while enhancing—their reputation as humane and philanthropic institutions for the care of the sick and injured. The most vital question in connection with medical education in this State, and indeed, in the United States, to-day is whether the great privately endowed hospitals of this city will recognize the immense opportunity which now stands open to them for self-improvement by offering positions on their staff to the best physicians and surgeons in America whom a medical school like ours desires to secure for every new or vacant professorship in its faculty. It is already too late for our hospitals to win the honor of being the first in America to adopt this policy. The hospitals of St. Louis, Cleveland, and Minneapolis have just made such arrangements with Washington University, Western Reserve University, and the University of Minnesota. Even the Province of Ontario, with a population approximately a quarter of the total population of the State of New York, or half the population of this City of New York, has already got ahead of us. I was in Toronto last Saturday attending the funeral of Goldwin Smith, and a gentleman with whom I was walking pointed out to me the site of a new hospital to cost $1,900,000, and he informed me that this hospital, which was being erected partly from individual subscriptions, but mainly from municipal appropriations, and which was to be maintained from the same sources, would nevertheless be in charge of a hospital staff under the appointment or control of the University of Toronto. Why should not one or more of the great, rich, and successful hospitals of the City of New York adopt on a scale proportionate to its strength and resources the policy which has already been initiated in these other American cities, which is in universal operation in Europe, which will be a source of incalculable profit and blessing to the hospitals, and which will turn the disesteem now attaching to medical education and medical research in our great City of New York into a fame and honor consonant with the greatness of our city and satisfying to the just expectations of the scientific world?

THE HEREDITARY AND CONGENITAL CAUSES OF EXCEPTIONAL DEVELOPMENT.*

By EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK.

INSTRUCTOR IN NEUROLOGY, COLUMBIA UNIVERSITY; VISITING NEUROLOGIST TO THE NEW YORK CITY HOME FOR THE AGED; SENIOR PHYSICIAN TO THE HOSPITAL FOR NERVOUS DISEASES OF THE CITY OF NEW YORK; NEUROLOGIST TO THE PENITENTIARY AND WORKHOUSE HOSPITALS.

In the brief twenty minutes allotted to me, I can, at best, only refer in a general way to some of the most important causes which tend to produce the exceptional child; those which are of minor importance I shall simply mention. I shall try to make the little I have to say neither too dry nor too scientific, and at the same time hope to interest you.

The causes which affect development, the factors which make posterity abnormal and unusual are largely those introduced and brought about by man. They result from the diseases which he has contracted through centuries, the poisons which he has imbibed, and the artificial surroundings and foreign environment which he has built up for himself. Nature does play some part in the development of exceptional individuals. It is, however, only in the direction of her usual course and in the execution of

*Read at a meeting of the National Association for the Study and Education of Exceptional Children, held in New York, April 21, 1910.

certain of her laws in which she is inexorable. Nature is doing more than this. She is ever striving to bring about the normal. While man is daily surrounding himself more and more with abnormal and unusual aids and an environment which he calls higher civilization Nature is constantly tending to revert to the normal. Whenever through the operation of certain factors there is produced a genius, at once there is a strong effort on the part of nature to revert to the normal. The next generation is of ordinary ability. The son of a genius is not a genius; the great man rarely leaves behind him a great son. Again, when elements of great degeneracy appear through the operation of certain other factors, nature soon renders succeeding generations sterile. If we take a large and comprehensive view of several generations we always find that the majority of both ancestors and progeny tend to a mean level, to a certain grade, characteristic of that family or tribe.

Of the causes which bear on the subject the most important is defective heredity; tuberculosis and alcoholism are next; then follow a host of smaller ones. A great many act in conjunction; a great many are contributory and indirect factors. Each tends to lower the vitality of the organism; each paves the way for its fellow.

The one which I wish to consider the first is also the one which all authorities are agreed upon as being the most important.

A defect in the ancestry, a pathological condition in the preceding generations is the most frequent, the most important, and the most constant cause of defective mentality in the next and succeeding generations.

This ancestral taint most frequently takes the form of a disease of the nervous system. It may be a cerebral hemorrhage, a neurosis, or a paralysis; it most frequently is insanity, imbecility, idiocy, dementia or epilepsy. The statistics which have been collected on this subject show great unanimity. In Norway it was found that in the cases of those who were sufferers from defective mentality the ancestry showed a defective heredity in 50 per cent.; in Switzerland 55 per cent.; in Germany 60 per cent.; in England and in America the percentage was below this, being about 43 per cent. These figures are all, however, sufficiently near together to show that so far as statistics prove anything there is a general unanimity of opinion in regard to the importance of morbid heredity as a cause. It is fair to say that it is the cause in one-half of the cases; I am inclined to think that this is a conservative estimate, as I should put the figures much nearer two-thirds.

Of all the causes of a morbid heredity, two stand out pre-eminent—idiocy and insanity. The one a mental defect, the other a mental disease. Each tends to transmit a most lasting and a most blasting heritage. Each attacks the entire structure, poisoning alike the mental, the moral, and the physical. Each enfeebles the judgment, each exaggerates the sexual impulse. Each tends to unite with any other latent neurosis. And finally each tends to transmit for many years. There are probably no human characteristics so baneful and none so readily transmissible as idiocy, imbecility and insanity.

It seems strange that I should have to give so prominent and so pointed a place to imbecility as a cause of propagating itself. And yet it is unfortunately too true. There is no greater stigma on the human race, no greater disgrace to civilization and to nineteenth century advance than the simple statement that imbecility and idiocy are the causes of further imbecility, of idiocy, and of profound degeneracy in a large number of cases. Koch gives it as the etiological factor in 24 per cent. of the cases.

Imbecility, idiocy, and insanity are not to be considered as the sole hereditary factors. The mere tendency to these conditions, the mere presence of a distinct neuropathic diathesis, the mere existence of an unstable equilibrium may suffice as etiological factors. They may outweigh Nature's efforts to revert to the normal, and if uncorrected by the infusion of good stable nervous tissue, may conduce to further degeneracy and ultimate ruin. Defective environment will here assume an important rôle; it may overcome the ever constant pull to the normal. Modern life, modern poisons, coupled with disease and the unequal struggle for existence, will aid in this destructive work. Finally, there will appear the lowest order of degeneracy. Then will Nature have recourse to her final safeguard. Sterility will follow and the house become extinct.

Another hereditary factor is epilepsy. There are few diseases which exercise a more baneful effect on posterity. A heritage of epilepsy is most easy to transmit; it is most difficult to eradicate; it may remain latent and skip a generation, but it always leaves its impress; it may reappear as epilepsy or it may bequeath to the next generation a neurosis, alcoholism or a more definite stigma of degeneracy. The child of the epileptic is almost sure to present exceptional characteristics. Therefore, epilepsy should be regarded as being a prominent factor in the production of the exceptional child.

Of the diseases which tend to produce exceptional children the tubercular are the most important. No disease does more to lower the tone and to lessen the physical forces than phthisis—the white plague. The peculiar condition of malnutrition which the tuberculous diathesis produces, seems to do more than almost any other factor to bring about an imperfect development of the nervous centers; it seems to transmit with greater ease than any other disease defective nervous tissue. Ireland say that perhaps two-thirds of all idiots are of the scrofulous constitution. I think that the men who take care of the deficient and feeble-minded will tell you that the most common condition which they have to treat is tubercular. Again, is phthisis very important from an etiological point of view, because it is peculiarly liable to cooperate with any latent neurosis of heredity or to emphasize any existing neurotic taint. Either alone or in conjunction with a neurotic diathesis phthisis is to be dreaded. It is a potent cause of bringing about children of exceptional development.

Dr. Hrdlicka made an analysis from the records at the State Asylum at Syracuse. He found that among the parents of the feeble-minded of whom he could get fairly reliable records, that 20.2 per cent. of the male, and 33.7 per cent. of the female succumbed to consumption. This is an enormous percentage, and probably twice as high as any other statistics on this question. I merely mention it because it will fix in your mind the great importance of the tubercular diathesis as a factor.

Cancer, goiter, and diseases of the cardiovascular system have all been given a place by writers on the subject. They do weaken the body structures; they must tend to bring into the world tissue that is far from normal.

I approach the question of intermarriage with some trepidation. There is no question, however, that is more interesting and certainly none of more practical importance.

Many writers have maintained in the past and many to-day maintain that a marriage between first cousins will promote degeneracy and bring into the world hereditary defectives.

Esquirol says that the number of French nobles who, as a result of intermarriage, are defectives is very large. Members of the laity frequently cite the royal families of Europe as affording proof that intermarriages tend to produce abnormal and deficient offspring. The members of some of the Spanish and Austrian houses have intermarried to a large extent; a review of the members and of the different branches of these families shows existing a large percentage of degenerates. Bemiss reported 833 consanguineous marriages; these were all carefully followed, and exhaustively studied. The degree of relationship was of every possible kind, even involving father and child. From these 833 marriages there sprang almost 4,000 children. Of this number there were over 1,000 defectives.

Now, let us look at the other side. Batz is an isolated, ocean-washed peninsula of the Loire, containing about 3,000 inhabitants. They are neither intemperate nor criminal. They lead simple lives. They are well known for their tendency to intermarry. Voisin reported 46 consanguineous marriages in this commune of Batz, yet he could not find a single instance of either insanity, idiocy, or deaf-mutism. Degeneracy among these people is unknown.

It is well known that among the North American Indians intermarriage is not the exception, but the rule. Mr. Bonsall, who was on the last Kane expedition, says that the Eskimos of North Greenland for centuries have intermarried. The same state of affairs is true concerning the South Sea Islanders, and many other savage tribes. Yet it is a well known fact that among these tribes instances of exceptional and unusual development are rare.

Frederick the Great, together with his remarkable brothers and sisters, was the offspring of first cousins. The great Queen Isabella came from strongly inbred ancestry.

I might go on in this way for some time quoting instances on both sides proving little, and only wearying you. The gist of the whole matter is undoubtedly in the fact as to whether the families in whom the intermarrying occurs have good or bad heredity. In the cases of the royal families it should always be clearly before us that for generation after generation there have been imbeciles and degenerates. On the other hand, in the savage tribes the stock has been good, clean, and strong.

I believe that the consensus of opinion to-day is that the consanguineous marriage is not in itself a cause of exceptional development; it may become so, but only when the two contracting parties are descendants of defective stock. The consanguineous marriages serve to accentuate the family characteristic, be that characteristic good or bad. If the family trait is weak-mindedness the next generation will, as a result of the intermarriage, be more degenerate still; if, on the other hand, the family trait is mental strength, the next generation will be fully up to that standard, if not above it.

Langdon Downs says that he is "by no means sure that by a judicious selection of cousins the race might not be improved." I agree to this. I see no possible objection to the intermarriage of cousins so long as there is no defective heredity in the ancestry. If there is defective heredity I see the greatest possible objection.

The literature and the facts which have been collected on the subject of alcoholism as a factor in the production of the exceptional child are full of interest. What, for instance, can be more so than the statement made by Dr. Elam in "A Physician's Problem?" He says that on the removal of the spirit duty in Norway insanity increased 50 per cent. and congenital idiocy 150 per cent. Dahl spoke much in the same strain of the conditions in Norway. Forty years have elapsed since then and we know that in that time there has been an enormous decrease in drunkenness both in Norway and in the entire world. Yet there is an apparent decrease in the number of idiots.

And again this: It is the custom in parts of Scotland for entire villages to become intoxicated at certain times of the year, as for example, during the holiday season. The celebration of this season covers several days. We might then expect that the children born nine months later would be largely imbecile. No one, however, has ever observed this. This is true also of many other communities where the custom is for drinking to take place in entire communities at certain periods of the year, yet the succeeding children who are born nine months later in no way differ from those born in that community at other times and under more normal conditions.

It is, of course, practically impossible to get data which will throw any light on the subject of whether drunkenness at the time of conception in either parent has any effect on the unborn child; it seems to me that such as I have just narrated would be of some value in helping us to reach a conclusion. It ought to be especially so in the cases of some of the fishing villages, where the men are away for long periods and then return to vend their wares and spend their money. In none of these instances, I repeat, are the resulting children in any way different from their brothers and sisters. In this sense alcohol has, to my way of thinking, but little effect. I mean that the isolated debauch occurring at the time of conception can have little if any effect on the next generation. Langdon Down has laid much stress on this subject. He takes the opposite view and states that from personal enquiry he knows that the drunken condition of the father at the time of conception is a potent cause of idiocy.

Dahl thinks that brandy taken by the fathers at the time of conception is a potent cause of idiocy.

Ireland does not embrace nearly so radical a view on the subject.

In weighing this question it should always be borne in mind that the man who goes on a periodic debauch is apt to be the man who has a neurotic taint and who, as he gets older, will, in all probability, increase both the frequency and the periodicity of his indulgences. To my way of thinking it is not possible to prove that a normal man, who becomes intoxicated at the time of conception of his child, is acting as a direct factor in the production of an exceptional child.

When, however, we come to consider alcohol in its broader sense as a factor in the production of unusual and atypical children we have a very different matter. There can be no doubt, it seems to me, that the succeeding generations of alcoholic

parents are weakened physically, morally, and mentally.

Alcohol weakens the resisting powers of the different cells of the body; it forms an hereditary neurosis; it destroys the healthy tissues; it prepares the way for the unusual, for weakened and for degenerate conditions. It does more than this; it conveys its baneful effects to the next generation and sometimes to the third and even the fourth. It is often the direct cause of such conditions as epilepsy, migraine, and conditions of great depression.

Alcohol is a potent cause; it acts both directly and indirectly. Given a mild neurosis, add alcohol to it and the next generation will develop far more than a neurosis.

It should also be borne in mind that alcoholism is itself often nothing more nor less than a symptom, a manifestation of a disordered nervous system, an indication of a neurotic taint. When it occurs in this sense it is, of course, of itself not a direct cause but only an indirect one. However, in those instances, and they are many, in which alcoholism occurs in the parents there is going to be a detrimental effect on the children and on the grandchildren; the family is going to be affected by it. The man who drinks to excess is not the man to have children.

Nor do I believe that the marriage of children of alcoholics can do any good to humanity.

Syphilis is not a factor of great importance in the causation of exceptional children. There are scarcely any observers who have given it a place of more than two or three per cent. There is no doubt but that it does have the effect of lowering the vitality and weakening the powers of the cells. In the instances, however, in which syphilis is found there are frequently other and more drastic causes. One of the main reasons for the low percentage which syphilis occupies as an etiological factor no doubt lies in the fact that nature herself rebels at the prospect of transmitting the syphilitic heredity. She takes her own measures to remedy the impending evil. She produces still-births and short-lived offspring; oftener she blasts the unfortunates with the curse of sterility and miscarriage. Syphilis is more apt to be an indirect factor; the results not appearing until the third or fourth generation.

There are many other poisons which no doubt have a devitalizing effect on the human cell germ. There is neither time nor space here for me to discuss them. One rather important one I wish to mention. It is lead. A certain case is cited by Paul, so unusual as to bear repetition. The mother was free from any toxic or abnormal condition; the father was the victim of lead poisoning. There were 32 pregnancies. Of these, 12 were still-births and 17 died under the age of 3.

Most authors agree that the relative age of the parents at the time of conception is a factor. Duncan, for instance, was of the opinion that premature and late marriages were influential in the production of idiocy. Langdon Down found that in one-quarter of the idiots which he examined there was a disparity of more than ten years in the ages of the parents. I am of the opinion that a man produces better, stronger, and more intellectual posterity before forty rather than after. I believe that this is so because the average city dweller is a better man physically before forty. I believe that a great disparity in years has some slight detrimental effect. These are two causes, however, which do not play any great part in the etiology of the subject.

Finally, there are a host of minor factors, all of which play a part in the production of the exceptional child. These are modern life, with its late hours, its higher civilization, its greater struggles; poverty, deprivation, and hard work. A high degree of anemia and great mental exhaustion in the parents. There are certain telluric influences which cause Cretinism, which is really the expression of degenerative factors. I should not omit the mention of intrauterine conditions, which may result in the atrophy and sclerosis of the fetal brain, and so be the cause of an exceptional child. Those instances where a cystic degeneration, a faulty or maldevelopment of the brain occur are again illustrative as factors of faulty inheritance. They may be oddities of nature, but as such are rare.

The whole matter of the congenital causes of this subject can best be placed under two headings: (1) The abnormal condition of the mother, and (2) the abnormal conditions prevailing at the birth.

I do not believe that the mental condition of the mother during pregnancy is a factor of any importance in producing the exceptional child. A majority of women are very greatly depressed during pregnancy; at some time their condition borders on a melancholia. A few do actually develop such a condition. If their mental condition were to affect the embryo there would be to-day before me a room full of melancholiacs.

The question of shock and fright to the pregnant mother is a somewhat different matter. Baron Percy, the famous French military surgeon, states that at the siege of Landau, in 1793, 59 of the 92 children born within a few months of mothers exposed to the terrors of the cannonading and blowing up of the arsenal were abnormal. Down states that similar results followed the siege of Lucknow. Mr. Ishii, of Tokio, tells of an earthquake in Japan, the effect of which was to bring into the world a large number of idiotic and imbecile children. These are facts, and as such should be given due weight. On the other hand, it should be borne in mind that no similar observations have been made in our own country after either the surrender of Richmond or the great earthquake at San Francisco.

The question of maternal impressions I am going to leave for others to discuss. I believe it is one of minor importance.

The physical condition of the mother I consider to be one of great moment.

Any wasting disease in the mother is going to have an effect upon the embryo; any chronic or infectious disease is equally bad.

Feré found that by injecting a few drops of an alcoholic extract beneath the shell of the chicken's egg he could produce monstrosities. It is, therefore, more than probable that the ingestion of any considerable amount of alcohol by the pregnant woman will have a deleterious effect on the fetus.

It is well known that the women who work in the potteries of France, and who are of necessity exposed to lead, are very apt to, and do, produce deaf mutes and macrocephalics.

Other influences, which undoubtedly exist and do exert an influence over the embryo, but which are not so well established nor so well recognized, are a profound degree of anemia, great mental exhaustion, and physical deformities of the mother.

Abnormal conditions prevailing at the time of birth have some influence in producing the exceptional child. Their importance, however, as an etiological factor is, to my mind, overrated. Pressure on the fetal head, if very severe and intense, may cause a permanent injury. The forceps, if used for too long a time or in too severe a manner, may also injure the child. This latter factor is under present-day conditions rarely if ever a factor. There are instances where the deformed pelvis and a prolonged labor, both singly and together, may act as a cause in producing the unusual child. Asphyxia at birth may act as a cause; it must, of course, be very prolonged and intense; in this way the blood is not properly aerated and, therefore, may exert a toxic effect upon the cells of the brain.

I believe that these are all factors, but I also believe that they are factors which have been given too important a place in the etiological list; parents greatly prefer to think that their defective children are defective through the fault of nature and the accoucheur, rather than through the faults of their ancestors and their own shortcomings.

Primogeniture is often spoken of as a factor. I do not believe that the firstborn child is more apt to be the weak-minded one than the last born. But I do believe that if there is a defective hereditary factor that it will be more apt to appear in the eldest and in the youngest than in the intermediate children. This is probably to be accounted for by the fact that the reproductive powers of the mother in the case of the first born child are not well established; in the last have begun to flag.

The only thing to say about premature birth is that, all things being equal, the seventh month child is more handicapped than the eighth or than the full term child; I mean that if an hereditary taint does exist, the premature child is more apt to succumb to it than the one at full term.

THE PARADOX OF THE TUBERCLE BACILLUS.*

By IRA VAN GIESON, M.D.,

NEW YORK.

This paper may be prefaced by giving the results and conclusions of a study of acid-fast particles associated with and subject to confusion with the tubercle bacillus, both in sputum and in tissues. These particles simulating fragments of the tubercle bacillus are of rather rare occurrence in casual examination of sputum with Ziehl's method, but in systematic examinations of large numbers of sputa in sanatoria the acid-fast particles appear quite frequently, say in 5 per cent. of the daily examinations. The particles give precisely the same reaction in Ziehl's method of staining, as the tubercle bacillus itself and apparently have the same degree of acid-fastness in retaining the dye. The particles, as a rule, take the form of minute spherical or slightly elongated points like tubercle bacilli in miniature, or show in various intermediate stages up to larger and coarser and sometimes budding tiny droplets of the same brilliant red hue as the tubercle bacilli. These particles occur quite uniformly or in more or less densely packed spherical aggregations inclosed often within a rim or halo made by their delimitation from the surrounding material of the sputum. Struck by the peculiarity of the enclosure of the particles as if in a hollow spherical envelope, and by their exceedingly capricious appearance in sputum sometimes suddenly appearing in and vanishing equally abruptly from persistently negative sputum and noting, also, the fact that these acid-fast particles failed to infect guinea-pigs or to develop in appropriate culture media, we accepted the idea that such particles might be fatty food globules making their way into the sputum when coughed up immediately after a meal. This probatory conjecture for the explanation of the particles turned out to be correct, for in examining various fatty elements of food, such as milk, fatty soups, and raw oily foods, precisely similar structures were seen under the microscope when stained with Ziehl's method and decolorized with acid alcohol or Pappenheim's rosolic acid solution. These fatty foods then, especially milk, are liable to contaminate sputum in a highly irregular fashion and to appear as if they were fragments of or aberrant developmental phases of real tubercle bacilli.

In old cheesy material, notoriously difficult in a demonstration of tubercle bacilli, the same mistake is liable to be made, for this material, as might easily be demonstrated by osmic acid and other staining methods, contained numerous fat droplets and probably a variety of the fatty acids and derivates. Among these are certain members of the fatty series the particles of which are acid-fast and may appear under the guise of derivates of the tubercle bacillus, as exhibited before you in the large scale colored sketches copied from camera lucida drawings with the microscopic slides chiefly of bovine lymph node cheesy material.

Feces, containing as they do, palmitic, stearic, and some eight other fatty acids, show these acid-fast fatty particles quite frequently.

The importance of recognizing the fatty character of these confusing acid-fast particles associated with the tubercle bacillus is obvious in practical laboratory diagnosis in the examination of sputum, feces, abscesses, and the like. Besides the possibility of diagnostic errors in cheesy material the proper appreciation of these particles is additionally important because of the mistakes in the literature of the degenerative and reproductive cycles of the tubercle bacillus, which has recently received a fresh and voluminous accession under the stimulus of Much's dubious work of the subject. Schrön, D'Arrigo, Spengler, and others seem wholly averse to the consideration of the real nature of these particles which so readily masquerade in the false role of conjectural "capsules," "granules," and "splitters" supposed to represent degenerative and reproductive phases of the tubercle bacillus.

It is not within the plan of this brief initial communication to give a critical analysis of the literature in which these confusing acid-past particles have been mistaken for phases of the tubercle bacillus, or to detail the literature pertaining to the misapprehension of the paradox of the tubercle bacillus. I wish at present only to express to you the conviction forced upon me by certain experiments and studies to be detailed later, that both subjects have been dealt with erroneously.

What is meant by the paradox of the tubercle bacillus seems too familiar to need any extended explanation. This paradox is synonymous with the

*A preliminary communication from the laboratory of the Otisville Sanatorium of the Department of Health of the City of New York. Read at a meeting of the Medical Association of the Greater City of New York, May 16, 1910, and accompanied by some thirty large wall chart illustrations.

contradiction encountered in finding no tubercle bacilli under the microscope, and still proving their presence by the results of animal inoculation with companion portions of practically identical material.

This has been an old and puzzling paradox to students of tuberculosis, and they have known for some thirty years that old, cheesy material, for instance, of bovine origin, especially, must contain bacilli in some form because it was virulent. But in spite of this, they were unable to demonstrate them under the microscope in smears or sections. The bacilli, or the remains of them, seemed absolutely invisible by the conventional method of demonstration. The most reasonable explanation of the paradox would be that such elusive bacilli had lost their acid-fastness, and then the puzzle would be simple, for such forms would be practically invisible with the methods current for their recognition.

According to his followers, who have built up quite a formidable literature, the prize of solving this important problem belongs to Much. This observer in comparing and contrasting the several methods for staining the tubercle bacillus, found that the ordinary method of Gram, not only appeared to stain more of the bacilli, but also stained here and there tiny granules and minute stavelets (stäbschen) alongside of them. Having thus gotten the hint that the invisible tubercle bacilli might be nonacid-fast, and at the same time of unusual form in minute spherical or miniature stave structures, he extended the intensity and scope of the Gram procedure by prolonged staining of hours instead of minutes.

Applying the modified method to material which was absolutely barren of bacilli by the conventional Ziehl method, it was no great task to convince himself and a good many others that these invisible bacilli had simply escaped detection by methods depending on the property of acid-fastness by losing this quality and had become transformed into these unfamiliar structures of isolated, apposed, or clustered granules and tiny stavelets.

Accompanying Much's work are experiments, which at first glance seem to grasp the question indisputably, although in reality they are extremely loose in catechising the phenomenon and are wide open to sources of error. These experiments consisted, quite naturally in planting bits of the seemingly barren tubercular material in culture media or in the tissues of animals, and from time to time with suitable staining technique watching the proliferation of the nonacid-fast miniature forms of the bacillus and their transformation into the familiar and classical structure of the bacillus in its acid-fast form.

Through abundant corroboration of Much's work, the problem now appeared to be settled and to epitomize the whole matter, the bacillus is regarded as having under certain circumstances a cycle in which, roughly speaking, one-third of its life history appears in a nonacid-fast form eluding detection by our time-honored methods.

One indication alone of the value of this discovery is that this masked part of the life history of the bacillus is coincident with the phenomena of latent tuberculosis, and a revival of the theory of the transmission of the bacillus in this form to offspring is at hand.

If the teaching of this school following Much is true, its importance is secondary only to the discovery of the tubercle bacillus itself. But I feel that a good deal of this work of Much's and his inductions are so fallacious that far from settling and solving the problem he had not even properly approached it, but the contrary had added confusion to the subject.

Much, it appeared from the speaker's investigation on the subject, had fallen into one of those cleverly masked traps which beset every turn of the scientific investigator, whose excuse that truth is often gained by the pursuit of error, is but a poor quibble of the fact that truth is gained through the pursuit of *corrected* errors.

The pitfall in this problem seems to have been the assumption as determined by the monographs, and conscientiously repeated in the text-books, that cheesy material and the like, in tubercular lesions is dead stuff; it is structureless, amorphous, and contains nothing but the ashes of coagulation necrosis.

Consequently, when these tiny bits of chromatin were disclosed in this supposedly lifeless material, it was natural to regard them as the only living constituent of this material; viz., the phantoms of tubercle bacilli, especially since these chromatin particles were the images of what tubercle bacilli might be expected to resemble on the supposition that they had disintegrated or had lost their acid-fastness besides, although not their vitality to culture, nor their virulence to susceptible animals.

The only trouble with this accommodating theory is that it appears to be wrong. Far from having this degradation of structure and being devoid of chromatin life, cheesy material, the avatar of the invisible tubercle bacillus when studied with especially devised technique showed an amazing complexity of organic structure, and a wealth of chromatin particles emerging from hosts of leucocytes in all stages of degeneration. It was truly remarkable to witness (as shown in the wall chart illustrations), the persistence of these degenerating leucocytes with their hosts of extruded chromatin filaments, and myriads of "granules," and "stäbchen" mimicing perfectly what might be expected of degenerating nonacid-fast tubercle bacilli.

Much and his followers seem to have fallen into the old makeshift of setting up cell degenerations as scapegoats for the real article where causal organisms are suspected or badly wanted.

The Much school seems open to this criticism: if they had not eliminated the products of cell degeneration they had not grasped the problem; if they had mistaken these degenerations for aberrant tubercle bacilli or confused the two, a serious blunder had been made on account of the very grave importance of the subject.

Undoubtedly in many of his preparations among the structures described by Much are involuting or aberrant types of tubercle bacilli; but the critical point still remains, that he has not eliminated the mimicry of granules and strands from the surrounding dying or degenerating cells. Quite likely also in some of his preparations he saw no vestigeal bacilli at all, but only their Dromio-like particles.

I feel that Much has not guarded himself against the similar mistake of considering the several "bodies" in cancer, variola, scarlet fever, trachoma, etc., as the real transmission organism. These, I believe, have been clearly shown to be degeneration products. And when these degenerations are dragged in under a brand new label in tuberculosis, it seems time to protest. Besides this, in Much's work the laxness of the experiments, the absence of illustrations, so that one could determine precisely just what the observer was talking about, and

above all the looseness of language seem hardly commensurate with the seriousness due the consideration of a problem of this magnitude. Tuberculosis is the most important of all diseases, and its most important factor is its early recognition, and one of the most, if not the most important factor, therefore, in this is the detection of the tubercle bacillus.

THE USE OF INTERNAL ALUMINUM SPLINTS IN THE TREATMENT OF FRACTURE.*

By WILLIAM S. THOMAS, M.D.,

NEW YORK.

No matter how far the operative treatment of fracture may advance toward perfection, there will, doubtless, remain a large majority of cases best treated by ordinary splints and massage. There will also remain a class of border-line cases where a decision whether or not to perform an open operation will depend upon the surgeon's experience and views. W. A. Lane of London is the most prominent advocate of open operations in practically every case of fracture where the skiagram shows misplacement of fragments which cannot be reduced indirectly. Stimson stands at the other extreme and decries any attempt at open operation, except in rare instances. Meanwhile, the number of cases of fracture considered as amenable to open operation constantly increases.

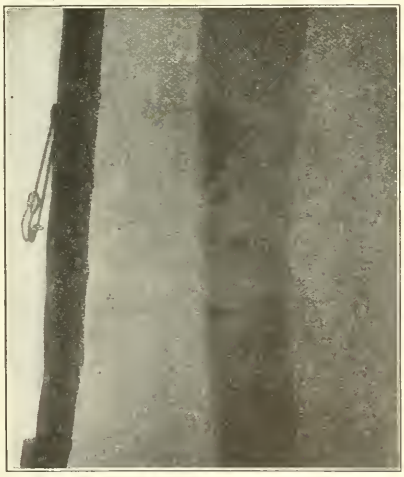

Fig. 1.—Skiagram of Femur with Internal Aluminum Splint in Position.

I will not discuss the *pros* and *cons* of this question, but will describe the method which appeals to me after experimenting with several, as the best operation for general use, namely: that which makes use of steel screws and aluminum plates. Steel screws are used because they have given satisfaction and are easily procured. The principal objection to the common wood screw in bone work is that its thread is not continued throughout its length. Screws answering these requirements, however, may be obtained of Allen and Hanbury in London. On the other hand, if a screw be selected whose point extends into the cortex on the opposite side of the bone it will not fail to hold the splint securely.

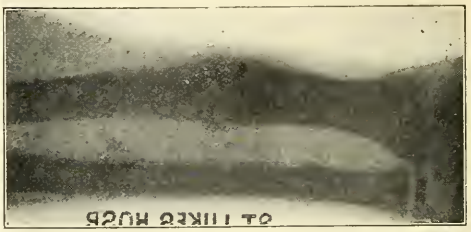

Fig. 2.—Skiagram of Internal Aluminum Splint with Callus Three Months After Operation.

Aluminum is the metal of choice for cleats because, while strong enough, it is easily worked into shape at the time of operation to suit any requirement. A piece of sheet metal of the proper thickness is selected and cut to an approximate shape with scissors. Three or four holes are bored in

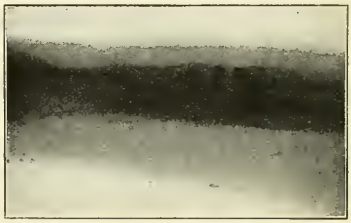

Fig. 3.—Side View of Fig. 2.

it with any sharp steel point and trimmed smoothly with a pocket knife and it is sterilized with the instruments.

Lane has multiplied the number of instruments for use in such cases and has devised steel plates of many shapes and sizes, but if aluminum be used it

Fig. 4.—Skiagram of Internal Aluminum Splint.

is easy to prepare it after the site of fracture is exposed and the particular requirement of the case becomes evident.

*Read before the Academy of Medicine (Section on Orthopedic Surgery), January 21, 1910.

Among the disadvantages of open operation for fracture are those due to the technique necessary with suture or intermedullary splints. Some of these drawbacks are obviated by the use of the aluminum plate. The great amount of trauma, necessary in

Fig. 5.—Side View of Fig. 4.

exposing all sides of the fragments for some distance from the fracture, so as to drill through the bone or apply a splint to its cavity, is quite done away with when a plate or cleat is used to hold the fragments in place. In the latter case it is not necessary to expose much or strip any of the periosteum. It suffices merely to expose enough of

Fig. 6.—Skiagram of Fractured Radius with Internal Aluminum Splint.

the fragments so that the plate may rest against them, without injuring the periosteum more than to puncture it for the screw holes. The ends of the fragments are held in place with a stout hook or elevator slipped under that one which needs to be pulled into place while the plate is being applied. The periosteum may be included between plate and bone without harm. The size of the drill bears a definite relation to the size of the screw which is to follow. A convenient plan is to use a mechanic's wire guage to measure the caliber of the screw which has been selected for use. Then a drill is selected two sizes smaller. This screw, when driven into the bone, will fit snugly and resist great force in attempting to dislodge it. With the plate lying in position, bridging the site of fracture, the drill is put through one of the holes in it and driven into the bone. A screw follows. With the plate now fastened in place as a guide the other holes are drilled in their proper places. The number of screws to be applied will depend upon the tendency of the fragments to become displaced, but there should be in all cases more than one screw on one side of the fracture. Otherwise, hinge motion will be allowed or the screws entirely dislodged.

It has been objected that the screws, acting as foreign bodies and irritants will cause absorption of the bone around them and thus become so loose as to be useless. This objection would seem to apply theoretically more certainly if machine screws with their shallow threads were used than will wood screws, with their deeper, coarser indentations.

Fig. 7.—Suture Ineffective in Overcoming Angular Deformity.

Those plates which I have used have held firmly at least until relieved of their work by natural union of the fragments. On removing both screws and plates I have found them to be firmly enough imbedded to necessitate being pried out of their resting places; but those which I have removed have all remained in place for many months.

W. A. Lane has gone so far as to avoid contact of everything with the wood except his tools and gauze sponges. Not even his gloved fingers are permitted to touch exposed bone or soft parts. His reiterated caution against carelessness in asepsis has caused some of his readers to suspect that he has had unpleasant experiences with infection. There is no doubt that strict asepsis is of great importance in these operations, but on the other hand, bone surgery carries with it no special predilection to infected wounds. Elsberg of this city, the inventor of the intermedullary aluminum splints, has even found pure aluminum to have a distinct antiseptic action. Certainly the danger of infection in the operative treatment of fracture will not be so great when trauma is not so great.

TONSIL RESEARCH.

By RICHARD B. FAULKNER, M.D. (COLUMBIA),

PITTSBURG, PA.

PREVENTIVE surgery is identical with preventive medicine as the great aim of modern medical research. The object of surgery is the restoration of physiological function. Surgery has no other object than to restore physiological action. Surgery often fails. "One in twenty bone operations on the nose will prove beneficial" (A. Jacobi, Phases in the Development of Therapy, *Medical News,* November 4, 1905). The best surgery is the least that is necessary.

George Crocker's legacy to Columbia University of nearly two million dollars for the sole purpose of research investigation into the cause and prevention of cancer, indicates a deplorable absence of knowledge upon this subject. And there are other fields in which the want of knowledge is equally deplorable, and in which there is urgent need for research light. Universities, and municipal and national authorities, are thoroughly aroused to the necessity of laboratories for original research in all fields of science. The nose, mouth, and throat need the light of physiological research. An increasing mass of literature pertains to the tonsils alone; permeated by conjecture, contradiction, and confusion. Physiologists know nothing of the faucial tonsils. Their textbooks do not mention them. Special investigators disagree. There is no accord —even as to the definition of a normal tonsil.

"The present period has been aptly termed 'the physiological era' of surgery. To succeed all operations must be based on accurate knowledge of all the conditions which make operative intervention necessary. The surgery of the future will have a lower mortality, not so much because of better technique, but because of better knowledge of the impaired function which it seeks to restore" (John W. Draper Maury, *Columbia University Quarterly,* March, 1909).

"Formerly, surgeons could not and would not perform many operations, which now are performed daily and with very little risk to life. On the other hand, physicians feel, and indeed believe they know, that operations, no matter how skilfully done and with what remarkable immediate outcome, do not invariably lead to apparent good results. They see recurrences, they remark unexpected deaths, they are not unfamiliar with painful symptoms later, which are fairly attributable to previous operations. Further, they ask, *cui boni,* to have an operation successfully performed and to return to the life and conditions which were unquestionably the occasion of the development of the disease primarily, and led to the necessity of an operation." (Beverley Robinson, MEDICAL RECORD, May 8, 1909.) "A surgical success; but the patient died," is a reproachful couplet, now familiar to all intelligent laymen. Operative surgery is overdone. Whenever a child is taken to a physician or specialist "there seems to be a tonsil, an adenoid, or an appendix which ought to come out." Political doctors pursue children even into the public schools, and send them away for operations upon their eyes, their tonsils, and their alleged adenoids!

Elaborate, systematic, research investigation has only just begun. When its light covers the entire field, and its enlightening rays stream into the mouth, the nose, and the throat, the foundations of intelligent laryngological practice, let us hope, will broaden; and the time may come when the question will be apropos, Does the surgeon need his knife? Henceforth, a surgical success must mean the restoration of physiological function. No more. No less. The man with a knife must succeed along the lines of physiological research, or he must not operate. "Just so soon as people can be made to understand that physicians are experts in the management of disease prevention, just so soon will disease be lessened and the sum total of human misery dependent thereon approach the vanishing point" (MEDICAL RECORD, November 28, 1908).

Faucial tonsils of healthy structure are constantly removed by laryngectomists. It is presumption to call all enlarged tonsils diseased. Without regard to function there is a growing habit of removing all tonsils, normal and abnormal—even in babies. "Their existence in the adult is unnecessary, and as they serve no good purpose, they are best removed, if they give the slightest trouble." (H. Holbrook Curtis, Voice Building and Tone Placing, page 72.) "The advancing popularity of the newer term, tonsillectomy, rather than tonsillotomy, is indicative of a general attitude favorable to total excision of the faucial tonsils" (Wm. E. Casselberry, *The Laryngoscope,* June, 1906). "For all these conditions enumerated, depending upon enlargement or degeneration of the tonsils, a positive cure can be guaranteed. No other condition of like importance in the whole domain of medicine is any more amenable to absolute cure than is this condition being considered, and the only rational treatment is surgical, viz., the thorough and total ablation of all hypertrophied or diseased follicle-bearing tissue. Arguments will be advanced that the loss of the tonsils may cause a permanent loss of the singing voice; that the tonsils are valuable bulwarks in giving protection against lung troubles, etc. It is needless to say that these claims enumerated, and all others of the same ilk, are thoroughly puerile and groundless" (Edward Pynchon, *Alkaloidal Clinic,* October, 1897). The complacency with which opinions are sometimes offered as matters of fact is interesting. "It is being more and more recognized that the complete enucleation of the tonsil with its investing capsule is the most satisfactory method of dealing with diseased tonsils. In the following indications it should be remembered that they are given with especial reference to the complete operation, technically known as tonsillectomy: (a) Nasal catarrh, and (b) Ear diseases, (c) Recurrent attacks of tonsillitis independent of ear or pharyngeal complication, (d) Repeated enlargement of the deep glands of the neck, (e) When the crypts of the tonsils are found more or less filled with débris and bacteria, (f) Laryngitis with attacks of hoarseness, crypts diseased, and tonsils hypertrophied, (g) Hypertrophy of the tonsils, (h) Chronic follicular tonsillitis, (i) Follicular pharyngitis, (j) Tuberculous infection of the tonsils, (k) Recurrent acute articular rheumatism following acute tonsillitis" (William L. Ballenger, Diseases of the Nose, Throat, and Ear, 1908, page 395). "Singers and public speakers, with a troublesome subacute laryngitis, whose tonsils are small and fibrous, or enlarged, may be benefited by the complete ablation of the tonsils" (Ballenger, page 364).

Ballenger's remarkable indictment of the tonsils, embracing the foregoing eleven counts, is fairly open to criticism. He presents total ablation as the

only appropriate remedy for all tonsil affections. Many, I believe, will consider this remedy needlessly severe, in a large number of cases. Research investigation and pathological classification seem forestalled, and differential diagnosis has no value when ablation is the sole remedy. The general indictment reminds us of the platitude found in "Science and Health and Key to the Scriptures" (1908, page 79), to wit: "The act of describing disease—its symptoms, locality, and fatality—is not scientific."

To offer tonsillectomy as a succedaneum for every tonsil affection, and for many pathologic disturbances of the pharynx, larynx, and ears as well, is not in keeping with the spirit of scientific research. Again, the strong advocacy of tonsillectomy is weakened by the hesitancy of Ballenger and the strong words of wisdom from his excellent text-book (1908, page 376): "It may still be questioned whether it is good practice to remove the tonsils in the wholesale manner now in vogue. The function of the tonsils in a child and in an adult is still an open question. The last word concerning the treatment of the tonsil cannot be spoken until its exact function is established."

Tonsil diseases are not fatal. But many die from tonsil operations. Tonsillectomy is always dangerous. Some surgeons consider removal of the tonsil more dangerous than removal of the appendix. "In all operations upon the tonsil we should remember the close proximity of the internal carotid artery (Gray's Anatomy, eighth edition, page 919). "Instances have occurred in which this artery has been wounded during the operation of scarifying the tonsil, and fatal hemorrhage has supervened" (Gray, page 491). The danger of scarification is many times amplified by tonsillectomy. The internal carotid supplies the brain, eye, and ear. Its ligation will interfere with the nutrition of these organs. "The arteries that supply the tonsil, from which dangerous bleeding also occurs, are the dorsalis linguæ, the ascending palatine, and the descending palatine, from the external carotid" (Gray, page 757).

Among the accidents which follow tonsillectomy are: Death from hemorrhage, from the tonsil, and also from the internal carotid; injury and laceration of the palatoglossus, palatopharyngeus, and superior constrictor muscles; severe infection of the wound (Ballenger, pages 411, 413); blood poisoning; inflammation of adjacent tissues; removal of one line of defence against microbic invasion (Ballenger, pages 361, 363); development of latent tuberculosis in adjacent glands and pulmonary tuberculosis (Ballenger, page 363); incomplete tonsillectomy with recurrent tonsillitis; extreme contraction of tissues; troublesome cicatrices; reflex nemoses: noises in the ears; affection of the tympanum: deafness; visual affection; alteration, impairment, and loss of voice.

Is the faucial tonsil an absorbent organ? Is it a portal of entry for microbic invasion? "In what manner and to what extent infectious material is absorbed by the tonsil appears to be a subject still open for active discussion" (Rufus B. Scarlett, Monthly Cyclopædia and Medical Bulletin, Philadelphia, December, 1908, page 667).

Dr. George B. Wood, in an article on "The Importance of the Upper Respiratory Tract in the Etiology of Cryptogenous Infections, Especially in Relation to Pleuritis (*Annals of Otology, Rhinology, and Laryngology*, December, 1908) states: "For an infection to start there must be some portion of the throat which may act as a gate of entrance. As lymphatic tisue is the tissue *par excellence* for the propagation of infection, it is natural that one should suspect the tonsils of showing lessened resistance. By the tonsils I do not mean the faucial tonsils alone, but also the pharyngeal and lingual tonsils, the lymphoid tissue of the lateral folds of the pharynx, and the lymph follicles of the posterior pharyngeal wall. However, as the faucial tonsils would generally represent by far the greater amount of lymphoid tissue in the throat, these structures are much more open to investigation, and hence the greater part of the work outlined in this paper pertains especially to them." Why Dr. Wood considers it "natural that one should suspect the tonsils" is probably for the reason that with many it has become a matter of habit to blame the tonsils. The case seems like the story of the boy who was twice arrested for stealing, and both times discharged for want of evidence, but, on the third occasion, he was convicted of suspicion.

"The faucial tonsils are much more open to investigation." True. It is also true that the other lymphoid tissues in the fauces and pharynx are exceedingly intricate in their distribution, cover large surfaces, and are vastly more difficult if not impossible to investigate thoroughly in regard to absorptive function. The great network of lymphatic structures in fauces, pharynx, and postnares, has not been thoroughly investigated by anybody. Beyond his preliminary statement, at the beginning of his article, namely, that "the faucial tonsils are much more open to investigation" than the neighboring lymphatic tissues in the fauces and pharynx, Dr. Wood makes no further mention of the latter structures, but quotes numerous cases, from many sources, alleging infection through the faucial tonsils as sole portals of entry. The lymphatic tissues of the fauces, pharynx, and postnares are very active absorbents. In not one instance, among the many cases reported by Dr. Wood, were these tissues said to be involved. Unless Dr. Wood can show by fair evidence that these tissues were not involved in the process of absorption, in any given instance, then it cannot be admitted that the faucial tonsils were the only portals of entry.

No investigator has ever succeeded in any instance in proving that the faucial tonsil alone was the sole portal of entry of an infection. This will be exceedingly difficult to prove, if at all possible, in a living subject. "We are seldom in a position to separate the tonsil from its neighborhood during the acute invasion or the rapid progress of a microbic or toxic poison. In cases of membranous throat disease, whenever the membrane is limited to the tonsil there is little or no glandular swelling in the neighborhood. On the other hand, if a membrane extends from the tonsil to its neighborhood, or starts at a distance from the tonsil, neighboring lymph bodies swell at once. Again, the treatment of this neighborhood shows its effect almost immediately on the swollen glands. That is mostly evident where the seat of the membrane is anywhere in the posterior nares which contain an immense network of lymphatics. These clinical observations have stood the test of time and must be reckoned with" (A. Jacobi, Tonsil as a Portal of Microbic Invasion, *Archives of Pediatrics*, July, 1906). Dozens of years ago I could prove that diphtheria when limited to the tonsils was least dangerous. The

thousands of other lymph bodies disseminated in the fauces and posterior nares are more guilty than the two dozen which form the tonsils. It is they that should be considered in the preventive treatment of all the infectious diseases of childhood" (A. Jacobi, Phases in the Development of Therapy, *The Medical News,* New York, November 4, 1905). It is reasonable to conclude that as long as a tonsil is normal, not inflamed, either acutely or chronically, it will behave more or less like a normal tonsil treated on the laboratory table. That is, almost like injection material, living invading material may enter the lymph circulation, or the blood circulation, provided there is a break in a wall, but not with the same facility as injection material forced in. A surface lesion must always be supposed to exist when a living germ or toxin is to find access. There is only one exception. Stoehr has shown small gaps between the normal epithelia of the surface of the tonsil. It looks rational, therefore, to admit that when there is merely a surface lesion, though ever so slight, there may be an invasion into the tonsil. When, however, the vessels are exposed to pressure by newly formed cells or tissue, there is no invasion, certainly not beyond the tonsil itself, no ganglionic swelling, and no toxic poisoning. It is even rational to believe that now and then, when tonsils, or what is more common, a single follicle, become inflamed, the very venous obstruction will exert the bactericidal influence of the stagnating blood serum.

Laboratory injections into the normal tonsillar structure are made under pressure, and prove nothing, or very little, for the unembarrassed organ when *in situ,* and surely not under pathological conditions.

Microbic invasion through the tonsil is not predominant over that which takes place through the lymph apparatus of the pharynx. Membranous affections limited to the tonsil cause no, or little, adenitis or constitutional symptoms.

The lymph current near the tonsils is less active than that of the pharynx at some distance. There are, moreover (Labbé), no lymphatic sinuses round the tonsil. There is a system of closed canals in the follicles which do not open into the connective reticulum. This observation of Retterer is confirmed by Hodenpyl. The external deep surface of the tonsil is covered by a firm fibrous capsule. This capsule is sometimes so disposed as to send along the tonsillar blood-vessels a network of fibrous tissue. It sends off connective tissue into and between the folds of the mucosa.

Exposure, and many diseases, change the surface and the structure of the tonsils. Cell infiltration and cicatricial tissue render absorption less possible. Blood and lymph vessels are compressed and undergo atrophy. That is why in advanced life the tonsil gets harder and smaller, and infections become less. (A. Jacobi, *Archives of Pediatrics,* July, 1906).

"The results of studies by Labbé, Retterer, Hodenpyl, and Most justify the conclusion that there are nets of lymph vessels inside the tonsil which do not open into the connective tissue reticulum, and that injections made into the region of the tonsil (not even into the tonsil itself) would not spread like those made into other parts of the nasopharynx. It would appear, therefore, that the tonsil and its immediate neighborhood are rather inferior, in regard to facilities for absorption, to the rest of the pharynx and nares, with their lymphatic pharyngeal ring."

Grober adds: "It is not possible, however, to remove the tonsil entire; besides, after its removal, there would be left behind, in the other parts of the lymphatic pharyngeal ring, apparatuses of equal anatomical and functional value which would assume the rôle of the tonsil" (A. Jacobi, Tonsils, or General Lymph Apparatus of the Pharynx, Which? *Archives of Pediatrics,* September, 1906).

The faucial tonsils are peculiar organs. They possess an anatomical character different from other tonsils, and from other lymphatic tissues. They are innocent organs, with functions chiefly confused by medical literature. Their blood supply is scant; and they have almost no communication with the lymphatic system. They are not absorptive organs; and no one has demonstrated that they contain any particular quantity or quality of antitoxic fluid, or phagocytes. Their crypts are lined by mucous membrane having the ordinary function of other mucous membranes so far as known. They are distinctly separated from the very active absorptive and bacteriolytic lymphatic structures of the fauces, pharynx, and nose. From the segregated position of the faucial tonsils; from the fact that the external deep surface is covered by a dense fibrous capsule; from the fact that this capsule sometimes sends a network of fibrous tissue as outrunners along the tonsillar blood-vessels (Hodenpyl); from the fact that the faucial tonsil contains a system of closed lymph canals in the follicles which do not open into the connective tissue reticulum (Retterer, confirmed by Hodenpyl); from the fact of the relative innocence of diphtheritic membranous processes when limited to the tonsil, and the absence of constitutional symptoms in these cases (A. Jacobi); from the fact that there are no lymphatic sinuses around the tonsil, and the further fact that the lymph current near the tonsil is less active than that of the pharynx at some distance (Labbé); from the fact that injections made into the region of the tonsil (not even into the tonsil itself) do not spread like those made into other parts of the nasopharynx (Labbé, Retterer, Hodenpyl, Most, Jacobi), the author concludes that the function of the faucial tonsil is chiefly, if not solely, mechanical. It is an important phonetic organ. It has other mechanical uses. It should not be removed without cause.

"Lymph nodes are structures so placed in the course of the lymph vessels that the lymph, in flowing toward the larger central trunks, passes through them, undergoing a sort of filtration. In the majority of cases, lesions of lymph nodes are secondary. The exact nature of these more diffuse masses of lymphatic tissue is too little understood, as indeed is that of the lymph follicles and glands themselves" (Delafield and Prudden, Text-Book of Pathology, eighth edition, 1907, page 442). "The nature of the process or processes of lymph formation is still a matter of keen debate" (Adami and Nicholls, Principles of Pathology, 1909, vol. 2, page 104). "The tonsils *appear* to have an important function" (Adami and Nicholls, page 392). They are not sure.

"A further important function (of lymphatic glands) is said to be the formation of leucocytes" (Adami and Nicholls, page 209). Again, not sure.

"I am disposed to think that the faucial tonsil in a healthy throat constitutes an organ of but trivial significance. That the tonsil, however, constitutes an intimate part of a healthy throat can scarcely be questioned in view of the admirable and exhaustive observations of Retterer" (F. H. Bosworth, Dis-

eases of the Nose and Throat, 1892, vol. 2, page 15).

"The organs of the human voice are related to many interesting inquiries in science and philology. In reviewing the writings of physiologists we observe defects which are obviously to be ascribed to the great complexity in the organization, and the real difficulty of the subject; but there are others which arise from the habit of resting contented with assigning one use for a part in the animal frame, whereas there is nothing which should more excite our admiration than the variety of offices destined to be performed by the same organ. This is especially true with regard to the organs of the voice" (Sir Charles Bell, The Organs of the Human Voice, Philosophical Transactions, London, 1832). "Every change in the shape of the passageway through which the voice is passed occasions a corresponding change in the quality of the voice" (Alexander Graham Bell, Mechanism of Speech, 1909). And no one can foretell what the change will be. The faucial tonsil is a natural organ, and should not be removed any more than any other natural organ. The mouth is an acoustic cavity. If you alter its walls, by removing the tonsils, you will necessarily change the voice. The faucial tonsil is an important phonetic organ; and it has, also, other undoubted mechanical functions. The great original work of Dr. Scripture in experimental phonetics, and of Professor Alexander Graham Bell, Dr. Henri Marage, and others, on the mechanism of speech, will enlighten, broaden, and improve the practice of laryngology. Medical and philological research regarding the faucial tonsils is badly needed.

306 Diamond Bank Building.

ANESTHESIA IN ITS RELATION TO THE GENERAL PRACTITIONER.

By H. W. KEARNEY, M.D.,

WASHINGTON, D. C.

Paul Bert has, not inaptly, likened the administration of an anesthetic to a journey along a narrow road beset with difficulties on either side, where an imprudent or ill-advised step to right or left may imperil life or prove fatal. And yet it is probably true that of the whole curriculum of our medical schools to-day there is not a subject concerning which the average graduate possesses less theoretical or practical knowledge. The majority of our colleges give the subject no place whatever—thereby implying to the student that it is one of minor importance, that anybody can give an anesthetic, and creating in his mind a sort of careless contempt for these powerful agents. From this attitude of complacency he is apt to be rudely aroused when for the first time he is brought to face some one of the alarming conditions which sometimes complicate anesthesia, with which he must deal promptly on his own responsibility, and to meet which he realizes his knowledge is inadequate. Is it surprising that the mortality under anesthetics has been heavy, and that it is perhaps increasing? It is true that anybody may give an anesthetic, and the patient may live (if he has luck on his side). So may anybody draw a picture which might be recognized as a man or donkey, as the case might be, but the work is not likely to be very artistic to say the least. Many an unoffending victim has been unduly and ignorantly "soaked" with an anesthetic and left to recover at his leisure, by the help of a long-suffering Providence and a good constitution. Here is undoubtedly to be found the source and reason for many of our cases of "ether pneumonia," aggravated nephritis, gastromesenteric ileus, acidosis, etc., so conveniently blamed on the anesthetic itself, for in these matters also Providence is apt to be on the side of the heaviest battalions, as represented by proper and careful technic. Safety in anesthesia cannot be attained without knowledge and experience, which means not only ability to detect untoward symptoms in their incipiency and make prompt application of the remedy, but ability to so conduct the anesthesia as to prevent their occurrence, in the ordinary case at least.

Our patients are as much entitled to the best of anesthesia as they are to the best of surgical talent. But many a physician will think his duty done if he spares no expense or effort to secure for his patient, who is about to submit himself to the trying ordeal of a grave surgical precedure, the very best operator he can find, assuring him, as far as may be, of accuracy in diagnosis, skillful, scientific surgical technique, and protection against infection, while he may not have given a second thought as to who is to take the life of his patient in his hands to guide him, for hours perhaps, along this narrow pathway separating safety from danger or death, under the influence of one of the powerful drugs which so profoundly modify the vital functions of the body as to produce the mysterious condition which we know as surgical anesthesia. He thinks only of the end, overlooking a very important means. His surgeon is capable—his anesthetist may be inexperienced, a student who has not studied, a layman, druggist or what not—anybody. It is not at all an uncommon event to find such a patient approaching his operation in a most distressing condition of nervous dread of the anesthetic, as compared to which his fear of the knife is as nothing. He may know from former experience, or from friends, something of the suffocation, choking, strangling, and the miserable nausea following many a faulty administration, and the feeling of his utter helplessness even to protest in any crisis that may arise unites with this knowledge to produce a mental condition which presents a very real difficulty to the anesthetist. The patient has confidence in his surgeon. He should have opportunity to know, or reason to trust, his anesthetist as well, thereby removing to some extent an element which often modifies the success of the whole operation much more than is generally appreciated, viz., fear of the anesthetic.

Like many other branches of medical science anesthesia is advancing, and the time is not far distant when its proper relation to the surgery of to-day will be more fully and generally recognized. It is true, however, that for a good many years real progress has been slow, and until comparatively recently the question of anesthesia and anesthetics has been as old straw threshed over and over, yielding only an occasional grain of added truth or fact to our knowledge. A reason for this is not far to seek when we consider the indifference of the profession in general, and that it has been the custom invariably to refer all inquiry on the subject to the surgeon as the one entitled to speak with authority. The studies and observations of our surgeons have been of great value, but as a matter of fact the surgeon, whose mind is engrossed with his operative work, technique, and concern for results, has neither time nor opportunity to note the changes his patient may be undergoing as the result of the anesthetic,

and it not in a position to draw reliable conclusions, or to work out and apply details of administration. With him the anesthetic cannot be the first consideration, and his impressions are based on effects rather than on incidents as they occur, which combine to produce these effects. The experienced anesthetist was seldom heard from. In fact experienced anesthetists have not been plentiful, principally because of the attitude of medical men toward him and his work, belittling his position, withholding their support, restricting his freedom, dictating his treatment of his patient, mistrusting his judgment. There has been little inducement or encouragement, pecuniary or otherwise, for the capable or ambitious medical graduate to devote himself to work along these lines. From the standpoint of credit due it has always been the operator alone who has been named and lauded for great results obtained, for cures wrought, for relief given. The position of the anesthetist has been a thankless one and if he were named at all it would probably be to raise a question as to his reponsibility for a death on the table "under the anesthetic." But to-day the medical press, at home and abroad, is arousing the profession to a fuller recognition of this neglected subject, urging the appointment of experienced men in hospitals, a proper training of students in our medical colleges, and sufficient requirements by licensing boards. The work of such men as Clover, Hewitt, Boyle, Buxton, Luke, Bennett, Allis, Gwathmey, Teter, Cunningham, and many others, has brought to light many important and impressive facts. As a result the mass of laymen is awakening and the obscurity of the background beyond the brilliant light of the "miracles and wonders" of modern surgery is clearing, so that all concerned may know something of the important modifying effect in surgery of a good or bad anesthesia. This is the era of the specialist and the day of the specialist in anesthesia is dawning.

It is impracticable, however, for all of us to be specialists, even if we would. Nor will we find it practicable always to have a specialist at hand when required, if we would. Every medical man will find himself called upon more or less frequently to administer anesthetics in the emergencies which arise in the course of his practice. It is one of the responsible duties which go along with the "rights, privileges, and honors" conferred by his diploma. Such being the case, while we are all as a matter of course interested in the fuller development and perfection of the many sides of this important branch of medicine, we should make it our business to familiarize ourselves with the effects, indications for, and difficulties attending the use of one or two anesthetics, and be able to give them reasonably well. Impressed with this idea, it will be the object of the writer to discuss briefly in this paper, in a general way, the two most common anesthetic agents, viz., ether and chloroform, to bring out a few points which seem of special importance, and, if space permits, a few general principles which he has endeavored always to bear in mind.

Since the period of their first introduction, some half century or more ago, ether and chloroform have rivaled each other for place in the surgeon's favor. At different times and in different localities they have alternated with each other as anesthetics of choice, one or the other having the advantage as some new fact has been brought to light, favorable or otherwise. Chloroform has nearly always been more popular in tropical countries for obvious reasons, also in Scotland where it was first used as an anesthetic. For the purposes of this paper we will pass over all history, the endless discussions relative to the merits and demerits of the two, reports of investigating bodies, etc., yielding the point that each has its own proper place in anesthesia, merely observing that the man who is thoroughly familiar with the use of both will obtain better results in general than from the exclusive use of either, and that in regard to these, as of all anesthetics, the personal element of the administrator himself is a more important factor than the particular drug or inhaler used.

In selecting an anesthetic for any given case we are influenced by several considerations—the safety, type, condition, and age of the patient, the nature of the operation, the skill of the anesthetist, the preferences of the operator, first and foremost in the mind of every conscientious man being the safety of the patient. For purposes of comparison of the toxicity of the several drugs mortality statistics are available, which have been made as reliable as possible and furnish a basis upon which we may work. The latest obtainable are as follows: Chloroform, 1-3,000; ether, 1-16,000; ether (by drop method), 1-30,000; nitrous oxide, 1-50,000; nitrous oxide, with oxygen, no deaths reported.

The most casual glance at these figures cannot fail to impress us with the evident wide range in toxicity of these three common anesthetic agents, and applying to our practice the principle which binds us to select the safest anesthetic possible for any given operation our attention is at once directed to nitrous oxide with oxygen. In the work of the general practitioner, however, the special, costly, complicated apparatus and skill required to make it satisfactory, the bulk and cost of the gases (about $5.00 per hour of administration), constitute a serious objection. But for hospitals and for special work there are numerous factors which seem to point to this as an almost ideal anesthetic. For instance, as regards safety in particular, we note that not a single death has been reported from the use of nitrous oxide with oxygen. It may be mentioned that Bellamy reports four million administrations in England in four years with no deaths. There are, perhaps, in America 100,000 administrations annually, so far without fatality. Martin has kept dogs anesthetized for three days without apparent injury. Gatch of Johns Hopkins has maintained anesthesia for five hours without so much as a headache following. It is not the intention, however, to attempt a discussion of these gases in this paper.

As between ether and chloroform our comparative figures show the former to be from five to ten times as safe as the latter in its immediate effects, and there can be little doubt that in after effects the ratio in favor of ether is still greater. Ether by the drop method is unquestionably the safest and most satisfactory routine anesthetic we have today for general practice. Given in this manner, with reasonable care, the element of danger is reduced to a minimum. It is a comparatively hard thing to administer a dangerous overdose without sufficient warning from the gradual failing respiration and changing color of the patient. When dealing with ether the practically simultaneous stoppage of respiration and circulation which may occur with the too rapid administration of chloroform is unknown if the patient be even moderately healthy, and however failure of respiration may arise, the

circulation of the patient, when breathing ceases, is sufficiently good for proper remedies to be almost always successful.

Ether is stimulating, while the essential characteristic of chloroform is depression, and though paralysis of the respiratory center is generally the cause of fatalities, it is often accompanied or very closely followed by paralysis of the circulatory center, and primary cardiac failure is not unknown. In fact, with chloroform, especially if rapidly given, the patient may die so suddenly that the order in which the fatal symptoms arose is impossible to recognize. In summarizing answers received to a circular letter sent by him to one hundred prominent American surgeons regarding a choice between these two drugs for anesthetic purposes J. E. Lumbard says: "They show that there has come to be an almost universal consensus of opinion in favor of ether, except in very special circumstances." Pulmonary and nephritic complications are on the whole no more probable under ether than chloroform. A great deal of experimental and investigating study of the pathological effects of ether and chloroform has been done in recent years, and much can now be authoritatively stated to the disadvantage of chloroform which heretofore was merely suspected. It has come to the point where the more experienced and better informed the physician is in regard to the toxicity of this drug, the more usually is he afraid of it and will refuse to give it except to a few exceptional cases. First, is its high primary mortality; second, its possession of an apparent selective action on the circulatory apparatus. Very sudden and unexpected diminution of blood pressure may occur at any time during its administration, and we can never be sure of the heart action; third, it is not only depressant to animal vitality, but is poisonous to protoplasm. According to Stiles chloroform causes, in some cases, fatty degeneration of the ganglionic cells of the heart and of the cardiac muscle fibers, the muscle cells of the body generally, the cells of the viscera and glands (particularly the liver), and the coats of the blood vessels. These changes may produce fatal results long after the drug has been administered.

Thus we see that chloroform not only produces narcosis but is capable of entire destruction of nerve and other tissues, causing first cessation of function, further on making it impossible of resumption. Of course, the most important factor as regards safety is that of dosage, which, if properly regulated, makes all the difference, but the margin between safety and danger is so small that the possibility of overstepping is never absent.

Of the after effects of ether and chloroform certainly the most frequent and that most complained of is vomiting. This varies from a transient nausea with a little mucus to prolonged retching and vomiting lasting for days. In this connection much depends on a careful preliminary preparation of the patient, next to which the amount of the anesthetic and manner of its administration will influence the result. Ether by the drop method, necessitating a large percentage of air with the anesthetic, avoids the cyanosis and carbondioxide poisoning which a closed inhalation adds to the irritation of swallowed secretions. In the writer's experience with this method ether nausea to any very troublesome degree has been nil. He believes that vomiting after ether in its worst forms is due, in a majority of cases, to an insufficient dilution with air, that sickness arises in much the same way as from the prolonged inhalation of any heavily laden carbon dioxide atmosphere, and that because of the character of the drug there is no more reason why a patient should be nauseated after he has rid himself of the ether-impregnated mucus which has been swallowed (which usually occurs before consciousness has fully returned) than after a moderate dose of alcohol. On the other hand vomiting following chloroform, while perhaps not quite so frequent, is apt to be more severe and prolonged, and arises not from local irritation of the digestive tract, but from interference with general metabolism. It is not nervous but toxemic in origin and due to more or less profound depression of the hepatic function, all the greater if the liver be weakened by disease. There appears to be little doubt that the prolonged vomiting sometimes seen after chloroform is but an early sign of the delayed chloroform poisoning which may, and often does, end fatally.

As regards nephritic complications, it seems to be fairly well established that neither ether nor chloroform are likely to produce more than a temporary albuminuria where there has been no preexisting renal disease. Nephritis and uremia have followed etherization in cases possessing unhealthy kidneys. The choice has usually fallen to chloroform in these cases, but the wisdom thereof is open to question and in fact both drugs are contraindicated in well-marked renal disease, or must be given with the greatest caution.

The question of glycosuria and acetonuria following ether and chloroform is of the utmost interest. Dr. Beesley of Edinburgh has done some valuable work along this line. A summary of the results of his observations on delayed chloroform poisoning would be of interest; but space forbids. The most important fact brought out seems to be that while both ether and chloroform invariably produce a temporary acute acetonemia, that of ether is less harmful because ether itself is less harmful to the cells of the liver and kidneys, and so does not interfere with elimination. It appears that very many cases of death a few days after operation which have been attributed to "septic intoxication" have really been due to acute acetonemia from chloroform, and failure of the kidneys to excrete the acetone with sufficient rapidity.

"Ether bronchitis" or "ether pneumonia" is the great bugbear and has been the pet argument of the chloroform advocates. The frequency of its occurrence has been very greatly exaggerated. Bronchitis and pneumonia do occur occasionally after ether, and no doubt many cases have been unjustly attributed to the anesthetic. A certain number of hospital cases will develop these troubles independent of any anesthetic, and in such their occurrence after the administration of ether may be mere coincidence; further they may arise from the use of dirty inhalers; from aspirated discharges from a septic nose, mouth, or pharynx, or vomited material; the operating room may be too cold, or the patient may be taken improperly protected through draughty corridors, or placed in bed near an open window. The proportion of cases of true ether pneumonia will be infinitesimally small under proper conditions of surroundings and administration. But while it is questionable if the refrigeration of the lungs from the inhalation of ether is ever in itself a cause of pneumonia, it certainly does mean a great expenditure of body heat at a time when this is much needed. When we consider that

the alveolar air space, in area something like 100 times the body surface, is being exposed to the icy vapors of ether, which the blood must warm to body temperature, the importance of this factor, as a predisposing cause of shock at least, appeals to us. Cunningham and Anderson have determined by careful experiment the temperature of inhaled ether vapor to be approximately 10° above zero, and have estimated that it requires 21,000 calories of body heat to warm each ounce of ether used. Expressed in other terms, sufficient energy in the form of body heat is dissipated during an ordinary operation under ether to sustain an average-sized man for a whole day. These figures are rather striking, and while it may not be practicable in general practice to adopt measures of warming ether vapor before inhalation, they impress us with the importance of conserving this energy for combatting possible shock by preventing unnecessary exposure during and after administration.

The deduction we draw from all the foregoing is that chloroform is an exceedingly dangerous drug to employ and should never be used for any operation which can be at all properly performed under ether. As absolute contraindications to ether may be mentioned active bronchitis, simple or tuberculous, latent or stationary pulmonary tuberculosis, and operations necessitating the actual or thermo cautery about the mouth. Aside from these the number of conditions in which ether may be satisfactorily given, which have been supposed to indicate chloroform, is surprising. It has been rather generally believed that women in parturition and young children enjoy special immunity from danger under chloroform, but this has been proven untrue and both women in labor and children will die readily if overdosed. It may be true that by reason of posture, high blood pressure, and stimulation of respiration and circulation by the pains, women in labor are fairly favorable subjects for chloroform, and on account of convenience and quick action it may be used in ordinary labor cases where full anesthesia is not required. But it should be remembered that the very same stimulus to full respiration which seems to protect may likewise menace through a quick overdose, and in all cases where operative procedures under full anesthesia are contemplated ether should be used if possible.

The difficulties and dangers attending this work must never be lost sight of. Personally I never give an anesthetic without having at hand such apparatus as may be required in dealing with emergencies, remembering that trouble is quite as likely to arise with strong, healthy individuals, who are more apt to resist and get an overdose, as with those who are comparatively feeble and yield readily to the drug. These things may not, probably will not, be needed, but, if they should be, delay while procuring means of treatment may mean the loss of the patient.

Dangers to life may arise primarily in connection with either respiration or circulation, but when conditions become really serious both of these great systems are usually involved. In the administration of ether it is the respiration which claims our first attention. Failure in this may be due to local or mechanical causes interfering with breathing, or to causes central in origin. The airways must be kept clear, and it is necessary to know by the sound of the breathing that such is their condition. A rule which soon becomes a sort of second nature should be that every expiration must be heard or felt in order to make sure that efficient breathing is going on. Unrecognized obstruction to breathing is one of the main elements of danger.

Mechanical or local obstruction to respiration may exist or arise anywhere in the respiratory tract. Polypi, spurs, deviations of the septum, etc., in the nose, valve-like action of the lips in the old or edentulous, falling of tongue against the pharyngeal wall, large tonsils, adenoids, abscess, foreign bodies, such as teeth, food, vomited material, or blood, which may be aspirated. I once relieved a man of his quid of chewing tobacco, and discovered a toothplate working toward the pharynx of a maiden lady who had indignantly denied the possession of any such perquisite to the nurse in the ward. Excessive mucous secretion may accumulate in the air passages. Spasm of the laryngeal or chest muscles from irritation of the anesthetic or from reflex causes; large abdominal tumors, tympanites or fluid in the cavities hampering the action of the lungs or diaphragm.

Symptoms develop suddenly or gradually according to the cause and completeness of the obstruction. Respiration becoming noisy, duskiness of ears and lips showing insufficient oxygen, and increasing until the patient is almost black in the face if the obstruction be complete, the pulse not altered at once but failing unless relief is obtained, and the respiration growing feebler and more irregular. The color of the ears and lips is to me a definite and reliable physical sign, denoting whether or not all is well, and in the use of ether these, with the character of the respiration, are observed more carefully than the pulse. It is not sufficient merely to see the movements of thorax and abdomen for these may continue quite long enough after air entry has become obstructed for damage to be done and serious asphyxiation to occur. Asphyxial factors must be differentiated as they arise and eliminated without loss of time, otherwise the patient will suffer, if not in loss of life, certainly in after effects.

Aside from obstruction, the respiration may fail from shock, loss of blood, or overdose. This will come on more slowly and be preceded by marked ashy pallor. Sometimes when an incision is made under light anesthesia the respiration may be stopped reflexly. Again in connection with the act of vomiting, under light anesthesia, the breath will often be held and temporary cessation of respiration result. This may occur at any time during an operation, especially if there be any manipulation of the abdominal viscera, but, though embarrassing, is not serious, for the anesthetist is master of the situation and the condition will rapidly improve if the anesthetic be pushed to a deeper degree.

Concerning circulatory difficulties it may be said that cardiac syncope, by far the gravest danger that can threaten one who takes an anesthetic, is practically unknown in the use of ether, but when it occurs does so almost always in the administration of chloroform. It may come not only in the weakly individual, but in the healthy adult male, and often when the operation to be performed is but a trival one. Many cases have followed chloroform given to a patient sitting in a chair for tooth extraction. It may occur at any stage but is most common at the very beginning. The most usual cause, the most fatal and the most difficult to treat, is overdose, though fright in the beginning and reflex inhibition during operative procedures are also to be mentioned. Much has been said on this subject by writers on anesthesia and several explanations have been brought forward. For our purposes, and

briefly, let it suffice to say that when in the early induction stages a too concentrated vapor is given to a patient, he holds his breath and struggles. The intrathoracic pressure is raised, the venous system congested, the arterial tension lowered, less blood and oxygen are supplied the heart and the heart muscle is weakened. Then comes two or three deep inspirations, for the breath cannot be held indefinitely. A large dose of chloroform is drawn into the lungs, passes to the already weakened heart which is thrown into an acute paralytic dilatation from which recovery is rare. Fortunately I have never had such an accident, but I have witnessed several deaths in young subjects from syncope under chloroform. In none was there any warning sign, but with startling suddenness the patient blanched, respiration and pulse failed, eyelids partly opened, and to all appearances death was almost instantaneous.

In the milder forms of syncope more warning is given and fortunately there is much more prospect of rescue. Death from failure of circulation other than syncope is probably due to the effect of the drug on the medulla, already anemic from lowered blood pressure which always accompanies the use of chloroform.

Treatment cannot be considered at this time further than one word, which should be a watchword—prophylaxis.

In conclusion the writer would say that he considers it the first duty of the man doing this work to be always (in slang parlance) right on the job. Certain classes of cases are, of course, attended with especial difficulty. These will naturally be treated with the utmost caution on the part of the anesthetist, and with all the skill he possesses. But it seems to me of the greatest importance for every man who practices anesthesia, if he would escape distressing accidents, to impress his mind with the fixed idea that every case is a study in itself, involving its own peculiar risks and dangers, with the element of danger never absent. Statistics will show that the majority of deaths occur at times and in cases where there seemed least reason to anticipate such a termination, often with the greatest suddenness, and in connection with operations comparatively insignificant. The work, then, calls for constant vigilance, together with the feeling that no case is too trivial to receive our best attention.

THE ENEMA—ITS PLACE IN THE TREATMENT OF GASTROINTESTINAL DISEASES.

By CHARLES J. DRUECK, M.D.,

CHICAGO.

In the preparation of this paper I have had a little misgiving lest the reader might think me a faddist on the use of the enema, as contrasted with other methods of treatment, but there is so much that is forgotten about the value of the enema that I feel I dare offer it as a subject for consideration. It is a method that is always handy and within your reach in any household. Given properly, it is absolutely without danger or bad after effects, and will never interfere with any other treatment of the patient. It is prompt and positive in its results. Its indications are found right along in daily practice from the restlessness of the baby, as a result of an over-filled bowel, to the saving of a life in cholera infantum or shock. This paper might have been labeled intracolonic hydrotherapy, but it is limited to the indications for the enema in the treatment of gastrointestinal disease, though I hope the reader will also see its value in the treatment of affections of the heart, liver, and kidney. I shall submit nothing theoretical, but shall attempt to present a few facts about the varieties of enemas and the indications of each, what they should contain, and a word about the technique of administration.

Simple Enema.—Let us first consider the simple enema such as is so commonly used to unload the bowel. For this purpose any form of syringe may be used and the water should be 95° to 100° F. This temperature causes the least reaction and peristalsis. The smallest quantity of water that will suffice must be used because the colon may easily be over-distended and the patient thus suffer irreparable damage. Large quantities of fluid should never be used as they produce atony of the bowel by over-stretching, just as atony of the anal sphincter is produced by stretching with the speculum. One quart of water should be the maximum and where we wish to stimulate peristalsis one-half pint of cold water is better than a large warm enema. To increase the effect of the enema, a teaspoonful of salt, molasses, or soap may be added, or one-half ounce of castor oil, glycerin, or oil of turpentine. Any of these added to the enema irritates the mucous membrane, removes the mucous from the bowel, and softens the fecal masses, thus aiding a prompt evacuation.

In atony of the bowel when a large part of the enema is retained, instead of being voided, the colon may be stimulated to contraction by applying a cold towel to the abdomen and lower back. If this does not suffice, the enema may be withdrawn by inserting a colon tube. An enema of a quart must never be allowed to remain in the colon, as it positively produces paresis; and above all, one should never add insult to injury by injecting another quart before the first is withdrawn.

If there is a desire to expel the enema prematurely, it may be controlled by pressing a folded towel firmly against the anus.

The simple enema to unload the bowel may be given with the patient in the sitting or recumbent position. In these positions the liquid is retained in the sigmoid and lower descending colon. Therefore, one quart is the maximum adult limit. One should always be careful in giving an enema not to introduce air into the bowel as that stimulates evacuation and sometimes causes colic.

Cold Enema.—By the cold enema is meant one with a temperature of 70° F. This much neglected enema should replace the simple tepid one very frequently because the cold water stimulates the bowel so much more powerfully that a much smaller quantity of fluid will serve our purpose. One-half pint of cold enema will unload the colon just as well as a quart of tepid water and by stimulating the muscle wall will leave the sigmoid and rectum in a contracted and anemic condition instead of relaxed and congested one. The cold enema, by stimulating the intestines, removes quantities of decomposing matter and toxins and increases the portal circulation. The reaction following the cold enema also produces a flow of fluid toward the intestine. In cases of chronic constipation or where hemorrhoids complicate the condition, the injection of one pint of cold water each day acts very well.

The cold enema is also a very valuable means of reducing the temperature in fevers and in typhoid fever it is an excellent means of stimulating the liver and kidneys, besides cleaning out the colon. The water is introduced through the rectal tube and should be injected slowly, the reservoir being about one foot above the patient's pelvis; it should be retained 10 to 20 minutes and then slowly let out through the tube and another quantity of cold water run in. This procedure is repeated two or three times without withdrawing the tube. It is well in some cases to begin the treatment with the first half pint of the enema at 90° F. and then steadily, but rapidly, reduce the temperature of the rest to 70° F. This helps the bowel to tolerate the enema and prevents its premature expulsion.

Hot Enema.—The hot enema or irrigation is used in the treatment of inflammation of the pelvis. It increases the blood pressure, accelerates the heart action, and stimulates the kidneys. The action on the kidneys and heart require a temperature of 110° to 120° F. An enema of 100° to 104° is of no use for this purpose. Following the hot enema it will often be noted that the patient voids a large quantity of clear urine. Kellogg places the hot enema superior to any diuretic drug in the treatment of suppression of the urine and Cantani and Wonte claim good results in the treatment of colic and infantile diarrhea.

The Coloclyster.—The purpose of the coloclyster is to introduce a large amount of liquid without over-distending the bowel. With the patient on his back not over three pints can be passed into the colon safely, but in the knee chest or Sims position six or seven pints may be injected without inconvenience. This is especially valuable in the treatment of pseudomembranous colitis, catarrh of the cecum, atonic and chronic dilatation of the colon when they complicate neurasthenia, autointoxication, and in collapse and shock.

Rectal Irrigation.—The chief advantages of irrigation over the enema is that a flushing may be given the parts. The first water introduced may be about the body heat and the latter rapidly heated or cooled as required to obtain the therapeutic results without causing sudden shock to the surrounding tissues. Hot irrigation of the rectum and sigmoid is useful in inflammation of these structures or surrounding tissues, in rectal ulcer, spasm of the sphincter, and in some gynecological affections. The water should be 100° to 125° F. beginning at 100° and raising to 125°. Normal salt solution (salt 1 dram to water 1 quart) is better than plain water to relieve local irritation.

I wish now to give you a brief outline of the therapy of colonic lavage in the treatment of a few intestinal disturbances to show the indications for the different forms.

Cholera Infantum and Cholera Morbus.—In the treatment of these diseases a hot enema (110° F.) may be given after each stool to remove the irritating and infectious material from the colon and reduce the frequency of the stools. To this may be added any necessary astringents, such as zinc sulphate, 1 to 3 grains to a 6-ounce enema, or an equal strength of silver nitrate or lead acetate, or 3 drams of bismuth subnitrate. Where there is a great deal of griping pain 2 to 4 drops of laudanum may be given in 2 drams of starch water. To reduce the fever a cold enema may be given as outlined above. For collapse a large warm coloclyster at 100° F. should be administered and retained.

Colic.—When the pain in the bowels is not due to inflammation but rather to pent-up intestinal gases or to enteralgia, the hot rectal irrigation gives good results. Also in ovaritis and salpingitis. If, however, the rectal irrigation is not convenient, the nurse can give the hot enema. One or two pints of hot water is injected into the sigmoid and colon and retained for five minutes. It is then expelled and more injected. This is repeated 3 to 6 times. The whole treatment may be repeated 2 or 3 times each day. The rectal tip of the syringe will suffice and the rectal tube is not necessary. The patient rests on her back to prevent the water passing high up in the bowel. With the rectal irrigator the hot solution flows out continuously as it enters. It does not distend the tissues but bathes all of the parts with the same temperature during the whole treatment. It is, of course, much more convenient for the patient and physician.

Colitis.—To cleanse the bowel we use a quart of water at 110° F. containing one-half dram of sodium bicarbonate and sodium chloride and flush out the colon twice daily. After each bowel movement we give a simple enema at 98° F. To relieve the pain and inflammation we give a cold enema at 60° F. to be retained 5 or 10 mniutes or, a cold rectal irrigation. This procedure may be repeated hourly, if needed. The cold enema or rectal irrigation, or even the cold anal douche, acts very nicely in treating prolapsed and irreducible hemorrhoids.

Chronic Diarrhea.—To lessen the congestion and stop the mucous stools we give an enema at 98° F., and follow it with a tonic enema of one-half pint of cold water, to be retained. To reduce the bacterial growth one or two large hot coloclysters should be given each day and followed with a small coloclyster of one pint containing gallic, or tannic, acid 1 dram. For the pain in the abdomen a hot enema at 110° F. after each stool is useful. For the alternate constipation and diarrhea a large, warm, simple, or soap coloclyster at 98° F. twice a week, followed by one pint of cold enema is advised. The general treatment consists in toning up the general digestion by regulating the diet and by means of the enema removing the masses of feces and mucus, and hords of bacteria, and with the small enemas containing gallic or tannic acid destroying the retained germs.

Peritonitis.—In the treatment of peritonitis the large coloclysters at 75° F., given three times daily assists very much in preventing obstruction, and if there is added one dram of turpentine it helps to evacuate the gas and relieve the tympanitis.

Constipation.—In the treatment of constipation the enema serves a great many different purposes, but it must be judiciously employed or it may cause more damage than good. Where the constipation is due to atony of the bowel, due to loss of nerve sensibility, the hot enema at 110° for 15 seconds followed by the cold enema at 60° F. for 15 seconds twice a day after breakfast, and at night, accomplishes a great deal. Or we may use the rectal irrigation. To increase the peristalsis the cold enema and the graduated enema by which the bowel is stimulated, or a gradually lessening enema is of much use. We should always avoid completely emptying the colon and also use a small cold enema instead of a large quantity of warm water, except when needed to relieve autointoxication, or to remove hardened or impacted feces. To remove fecal masses the hot coloclyster or enema of soap, oil, or glycerin (glycerin 1 to water 4 ounces) should

be used. The enema may have to be repeated several times, and should be given every hour until the bowel is thoroughly cleansed, and then a pint of cold water at 70° F. should be given to tone the bowel. The habit of the warm enema must be avoided, and it is well to make it a rule to give a small cold enema afterwards to tone up the bowel.

Typhoid Fever.—The treatment of typhoid fever presents many indications for an enema and yet I think it is many times forgotten. For the diarrhea a hot enema of 2 to 3 pints and after it is voided a cold enema of 1 pint is of value. For the constipation which sometimes displaces the diarrhea and for tympanitis and meningitis a copious coloclyster at 95° F. may be administered twice daily, and yellow soap or 1 dram of turpentine may be added to this. For the high temperature or delirium a cold enema at 70° F. to be retained for 15 minutes and repeat every 3 hours until the temperature reaches 102° F., is advised. But with a high temperature and a cold skin we have a different condition and we want the stimulation of a hot enema and the cold friction rub to the skin. For intestinal hemorrhage a rectal irrigation with ice water is of value and two days after the hemorrhage has ceased a cleansing coloclyster at 75° F. to remove decomposing blood clots from the bowel. Gastric irritation calls for the withdrawal of food by the mouth and the giving of nutrient enemata, but space forbids our taking up that subject here.

438 East Forty-sixth Street.

PRELIMINARY REPORT OF A STATISTICAL ANALYSIS OF OVER 43,000 CASES OF DIPHTHERIA.

By MARY SALLOM, M.D.,

PHILADELPHIA, PA.

The number of cases of diphtheria which has occurred during the past 12 years in Philadelphia, as reported to the Bureau of Health, has been 43,997. The figures may be considered quite reliable inasmuch as a majority of the diagnoses made was subsequently confirmed by a bacteriological examination. This is very well shown by the report of the Bacteriological Division of the Bureau of Health. Thus, in 1898, 5,536 cultures were made. This number gradually increased, when in 1907 as much as 14,297 examinations were made. This number is exclusive of the examinations made in the laboratory of the Municipal Hospital. To a certain extent the large number of cases examined for diphtheria bacillus is due to the vigilance exercised by the medical inspectors in their general work, and more especially to the constant supervision and study of the throats of school children.

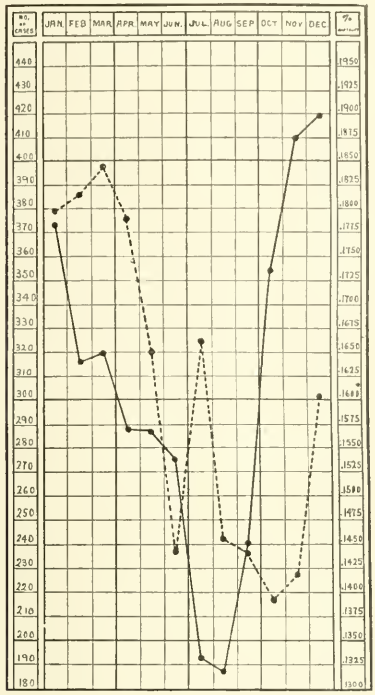

Chart I.—Show the average number of cases and the percentage mortality for each month of the year. Statistical analysis of 43,997 cases.

Of the 43,997 cases reported 7,097 died. From the etiological as well as the therapeutic stand-

Table I.—Showing by month the number of cases of diphtheria occurring in Philadelphia from January, 1898, to December, 1909, inclusive.

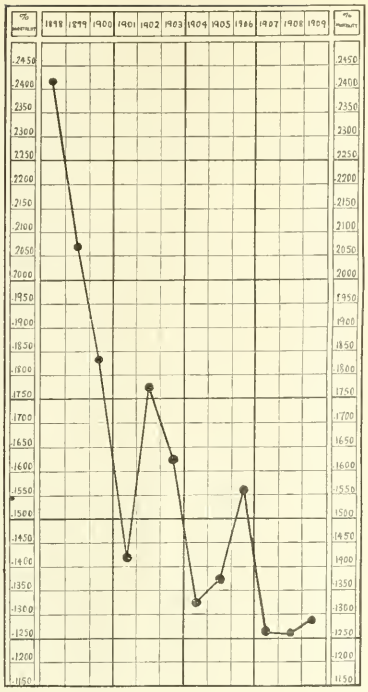

Chart 2.—Showing percentage mortality for each year. Statistical analysis of 43,997 cases.

point of view a study of so large a number of cases is indeed interesting.

Table No. 1 gives the number of cases and the mortality by months. At the foot of each column the total number of cases and mortality as well as the percentage mortality for each year is given. To the right of the table is given the total and average number of cases for each month. The percentage mortality for each month is also given.

Chart 1 graphically portrays the influence of season upon the disease. Starting with rather a high average of 374 cases for January it falls to 317 cases for February. Rising slightly for March it then gradually falls during April, May, June, and July, reaching its lowest ebb during August. From thence it rises very rapidly, reaching its maximum during December, which has an average of 419 cases. The percentage mortality for each month is represented by the dotted line in Chart 1. Starting with a mortality of nearly 18 per cent., it rises during February and reaches a maximum of 18.43 per cent. during March. It then rapidly falls during April, May, and June. During July it reaches its second maximum, being 16.66 per cent. During August, however, it falls again to nearly the same percentage as June. From thence it falls gradually, reaching its lowest mark during October. It again rises during November and December, reaching 16.03 per cent. for the latter month.

Chart 2 is of particular interest especially from a therapeutic standpoint. It graphically shows the mortality for each year. In 1898 the mortality was 24.18 per cent. For 1899, 1900, and 1901 it fell to 14.18 per cent. Rising to 17.75 per cent. for 1902, it then gradually fell during 1903, 1904, and 1905. During 1906 it rose 15.56 per cent. only to fall to over 12 per cent. during 1907, 1908, and 1909.

Aside from showing the percentage mortality for each year it also undoubtedly shows the important rôle played by antitoxin in the reduction of the mortality. It will be seen that as more and more antitoxin was used the mortality fell lower and lower.

To a certain extent the amount of antitoxin used in Philadelphia can be gauged by the amount which the city through its Bureau of Health distributed free of charge; thus in—

Year.	Amount furnished.
1898	3,367 doses
1899	2,976 doses

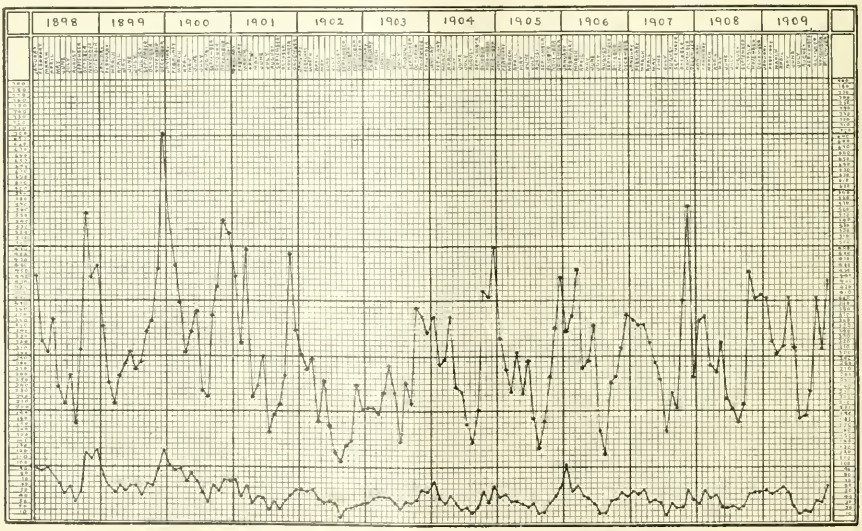

Chart 3.—Graphically showing the number of cases and mortality by months. Statistical analysis of 43,997 cases.

Year.	Amount furnished.
1900	5,233 doses
1901	5,374 doses
1902	5,771 doses
1903	7,342 doses
1904	15,500,000 units
1905	21,800,000 units
1906	34,000,210 units
1907	36,818,500 units

It will be seen that with the more extensive use of the diphtheria antitoxin the mortality has been reduced. This, I believe, is sufficient to the most radical adherents against the use of antitoxin of the therapeutic value of diphtheria antitoxin.

Chart 3 graphically shows the number of cases from month to month, and year to year. The upper line represents the number of cases, and the lower the mortality. Reading from right to left each space represents one month, and every twelve spaces are intersected by a heavier line marking off an interval of one year. A glance at the chart will show that in almost every instance the lowest number of cases is recorded about the middle of the year, and the highest number of cases during the early and late part of the year; showing that season undoubtedly exercises its influence in the same manner regardless of the total number of cases that occur during the whole year. This chart also shows the general prevalence of the disease from year to year.

1625 South Fifteenth Street.

CASE OF CONGENITAL FUSION OF TOES WITH NOTE ON PREVIOUS GENERATIONS.

By FREDERIC GRIFFITH, M.D.,

NEW YORK.

I once heard Dr. Reichert, my physiology teacher, relate that tailless mice could be bread if amputation of the caudal extremities was continued up to the eleventh generation. Hereditary influence seems proven in body conformation in some lower animals, therefore, however much it may be that it is environment rather than heredity which causes change or moral lapse from type of mind in the humankind.

While examining a first and male child, eleven months old, of good flesh and figure, I noted an

anomalous complete linear fusion between the second and third toes as pictured in the illustration. Both feet were included. The parents are healthy people, above the average size and intelligence. The mother claimed to possess a similar freak in one of her feet; she further stated that her own maternal parent was likewise endowed upon a single foot similar to what the grandchild had in both of his pedals. The fused toes were perfect otherwise, in having nails and joints and bones of normal size for age presented. Asked for the reason I could only recall that some scientist had given out that the human foot was destined from the shoes we wear to grow in time by fusion into a heel and sole, and single pointed toe and that, perhaps, now was shown an example of an advancement in the make of feet. I was jeered at for my pains. However, I will recollect the family difference in these people and will endeavor to note the feet of any future children and report thereon.

Syphilis of the Ear.—G. Berruyer says that syphilis in all stages may affect the hearing. It may affect the external ear just at it does any other portion of the skin, by the presence of papules or gummata. But the most important effects are upon the internal ear. In heredosyphilis there are suppurative conditions of the middle ear that accompany nasal and pharyngeal catarrhs of syphilitic origin. The specific catarrh of the new-born infants presents a portal of entry for secondary infections. Suppurative otitis appears as a complication a few months after birth, appearing insidiously, without pain, or general or local reaction. It may be bilateral, and in such cases is very likely to end in deaf-mutism. Later in childhood we find specific ulcerations of the nasopharynx, accompanied by inflammation of the middle ear and deafness with retracted drum. Again there is a dry otitis characterized by progressive deafness, which takes place in young people from twenty to thirty years of age. It may be accompanied by ocular or dental stigmata. Acquired syphilis shows itself in disease of the drum, the tympanum, and the Eustachian tube. Mucous patches at the orifice of the tube determine inflammatory reactions and obstruction of the tube. This form of ear trouble may be diagnosticated by its resistance to all treatment except antisyphilitic remedies, and the diminution of the osseous conduction, showing participation by the internal ear. Tertiary syphilis in the ear depends on nasopharyngeal lesions. In the internal ear we find deafness appearing suddenly without pain at the time of puberty, without any apparent cause. Deafness is absolute and prognosis is bad. In some cases it comes on slowly. Acquired syphilis causes deafness from obliteration of the arteries of the labyrinth. This form is accompanied by neuralgias with nocturnal exacerbations. It appears suddenly and becomes absolute very soon, with little hope of cure.—*Le Bulletin Médical.*

Myelogenous Leukemia in a Child.—Whiphman reports the case of a child eighteen months of age, who was healthy until one year old, when he began to waste. The father gave a history of untreated syphilis. The child was unable to sit up. The frontanelle was wide open. There was no bossing of the skull. The ribs were slightly beaded, but there were no epiphyseal enlargements. The lymphatic glands were just palpable and somewhat hard. The spleen extended to the middle of the abdomen, and four and one-half inches below the umbilicus. The liver was enlarged. The blood count was as follows: Red cells, 4,080,000; leucocytes, 63,400; hemoglobin, 80 per cent. The differential count showed: Polymorphonuclears, 32.4 per cent.; lymphocytes, 5.2 per cent.; large mononuclears, 18.8 per cent.; transitionals, 12.8 per cent.; eosinophiles, 2.6 per cent.; basophiles, 0.6 per cent.; neutrophile myclocytes, 25.8 per cent.; eosinophile myelocytes, 1.6 per cent.; normoblasts, 1.6 per 100 leucocytes. Subcutaneous hemorrhages occurred upon the extensor surface of the right arm, or the right shin, on the scalp, left ear, left eyelid, and left side of the face. The child had been under observation one month, and was getting worse; the leucocytes had risen to 101,000. The child had received *x*-ray treatment without evident effect. The author refers to thirteen known cases of myelogenous leukemia in children. The earliest reported was four months of age.—*Proceedings of the Royal Society of Medicine.*

Laryngeal Vertigo.—H. J. Davis reports this case. The patient described his attacks by saying that "first a tickling begins in his throat, he coughs and coughs for five or ten minutes, he then becomes violently giddy, and he falls to the ground insensible; when he recovers in a minute or two all desire to cough has gone, and he feels all right." Examination showed severe conjunctival hemorrhage, hemorrhage from dilated veins in the pharynx, hemorrhage into both vocal cords, and numerous bruises from falls.—*Proceedings of the Royal Society of Medicine.*

MUTUAL RELATION OF LIFE INSURANCE AND THE MEDICAL PRESS.

IN speaking at the annual banquet of the American Medical Editors' Association at St. Louis on June 6, Mr. Frederick L. Hoffman, Statistician of the Prudential Insurance Company of America, made some complimentary references to the work of the medical press in connection with life insurance. The speaker directed attention to the fact that so long ago as 1873 the MEDICAL RECORD made an effort to maintain a special department of insurance medicine, and that many of the most valuable contributions to the subject had never been reprinted in text-book form, and were, therefore, only available through the periodical medical press. He surveyed the field of medicine, and dwelt at length with the involved and increasingly important subject of occupation morbidity and mortality, alluding to the many suggestive discussions on industrial poisoning, industrial dust, and other dangers to life and health in industries treated of in articles and papers printed or reprinted in the medical periodical press. The insurance aspects of some rare, obscure, or new disease, including anthrax, leprosy, and pellagra were also discussed.

After referring briefly to the important problems of tropical medicine, Mr. Hoffman concluded by saying, "All of these illustrations are but mere fragments of a vast amount of extremely useful data, theories, and conclusions regarding the innumerable elements and factors, common or rare, which more or less have a bearing upon the science of insurance medicine. The perfection of the human understanding on the basis of the growth of human knowledge is necessarily slow, but it is sure towards the goal of ultimate truth. In this laudable aim and endeavor, the medical periodical press is rendering a most useful service, not only to life insurance medicine, but to the cause of scientific, sound, and solvent insurance throughout the world. Every contribution of fact and truth toward a broader knowledge and a more accurate understanding of the principles of insurance medicine has its value, which while not to be expressed in dollars and cents, is at least convertible into sentiments of genuine appreciation and gratitude, which I have tried to express on the present occasion. I trust that what I have said will prove an encouragment to those who labor unknown, and who are often discouraged and more often disappointed at the meager reward of editorial labors, and that you will carry with you the conviction that, though you may know it not, your work is appreciated to its fullest extent by at least the few, and, perhaps, by the many, who as medical directors, medical examiners, or in other positions of trust and responsibility, promote the cause of truth and progress in the vast domain of modern medicine and insurance throughout the world."

Such words as these are full of comfort and encouragement to the medical editor. As a rule, this individual obtains little recognition and less praise, in fact, there are those who hold that editorials in themselves are, in these days, superfluous and that all needed in the make-up of medical journals are merely scientific medical and surgical facts. This view, however, of editorial writing is superficial. An editorial should not only be used as the medium for intelligent comment on current happenings in the medical world, but should be an expression of opinion on the same. It must also be borne in mind that, at the present time, lay papers devote a considerable amount of their space to medical matters and copy or refer to any editorial of moment in a medical journal, evidence that the general public takes an interest in medicine.

STRAW ITCH.

OCCASIONAL outbreaks of a disease characterized by an urticarioid eruption and at times mild constitutional symptoms have been noted in several of the eastern and middle western States. The disease has been supposed, at times, to be due to "chiggers," or the "red bug." It has, also, been mistaken for urticaria and scabies, and in some instances the possibility of its being chickenpox or smallpox has been suggested. In 1901, Schamberg reported an outbreak in Philadelphia, and since then cases have been recognized there annually during the summer months. During the early part of the summer of 1909, Goldberger and Schamberg, in studying an outbreak among sailors, identified the cause of the disease as a small, almost microscopical mite in the straw of mattresses upon which the patients had slept or had placed their clothes. Working independently, and at about the same time, Rawles traced the cause of a similar outbreak in Indiana to the same mite. Goldberger has recently reviewed our knowledge on the subject in an article published in the Report of the United States Public Health and Marine-Hospital Service, for June 10, 1910. The mite has been identified as the *Pediculoides ventricosus,* which appears to be found commonly in growing and stored grain, where its presence is dependent upon the existence of certain insect parasites upon which it lives. The mite feeds on the larvæ and adults of these parasites, the most common of which so far as grain is concerned seem to be the joint-worm and the Angoumois grain moth. The mite, it appears, may, in the presence of an abundant food supply, increase enormously in numbers, so that those handling the grain in the field or in the process of thrashing, readily become infested.

It would also appear that the mite may be transported long distances in the straw and that, when this is used as a filling for mattresses, may escape through the ticking and attack those sleeping on them.

According to Goldberger, the mite does not bore into the skin, but simply attaches itself rather feebly to the surface where it bites, and probably while doing so injects a poisonous substance which produces the skin lesions and frequently mild constitutional symptoms. The dermatitis accompanied by itching, which is at times intense, has been described as consisting of wheals surmounted by small vesicles which, in the course of a few hours, become filled with pus. The eruption is reported to involve mainly the trunk, leaving the limbs, face, and neck little or not at all affected. In severe cases chilliness, nausea, vomiting, and albuminuria have been noted. The treatment of the affection seems to be exceedingly simple, due to the fact that the mite attaches itself so loosely to the skin that it is readily brushed off by the clothing or other gentle friction, the essential point being a recognition of the condition so that repeated exposure to the attacks of the mites may be avoided. The disease has been reported from various places in New Jersey, Maryland, Pennsylvania, Ohio, Indiana, and Tennessee. However, it, in all probability, has existed in a much larger territory than that indicated, and judging from the known prevalence of the grain parasites, upon which the mite depends for food, the disease may be expected to be of fairly frequent occurrence for possibly some years, especially in rural communities and the smaller towns.

Lactation in Omphalopagi.

The phenomenon of lactation is one which has caused no small amount of mystification to physiologists from the earliest days of scientific medicine. Recent investigations have pointed to three chief factors in the production of milk, which may be briefly summed up as follows: The growth of the breasts at puberty and especially during pregnancy is due to the stimulation from the internal secretions of the ovary; the production of milk is dependent upon absorption of some material produced in the placenta; and the continuance of the flow is caused by the mechanical stimulation of suckling. Such facts have been brought out largely by experiments on dogs, by transplantation of ovaries, and inoculation of placental extracts, by which means animals which had never been pregnant were made to secrete profusely of normal milk. Such observations are in the human being under ordinary conditions impossible. Recently, however, a natural anomaly has presented the opportunity for an observation which goes a long way towards confirming this theory as applied to man. A few weeks ago two women in Bohemia who were joined together in the manner which was made famous by the "Siamese twins" were admitted to the General Hospital in Prague, and shortly after admission one of the twins gave birth to a child. Basch, who has done much work on experimental lactation, observed the women carefully, and in the *Deutsche medizinische Wochenschrift* reports the interesting fact that whereas the woman Rosa was the mother of the child, and her sister Josefa had never been pregnant, both women were secreting perfectly normal milk from their mammary glands. The circulation of the two women being connected it is evident that whatever chemicals were produced by the pregnant Rosa were also circulating in the blood of the virgin Josefa, whereas any mechanical influence of pregnancy would affect Rosa only. This observation adds additional weight to the chemical theory of lactation.

The Action of the X-Ray in Large and Small Doses.

Since the discovery of the *x*-rays and their application to therapeutics, many and various results have been obtained from their use, results often quite contradictory in character, the explanations of which have at times been distinctly puzzling. It has been difficult in many instances to explain why in one case the use of the rays would cause degeneration and at others regeneration of similar tissues; why, for example, in one patient superfluous hair would be removed and in another the use of the rays on a smooth skin would result in a profuse hirsute adornment. In recent years, however, means have been devised of regulating the dose of the *x*-rays and of estimating in units the amount of radiation being administered in each case. This has made the study of the action more accurate and has enabled the illumination of several obscure points. In the *Berliner klinische Wochenschrift* for May 23, 1910, H. E. Schmidt reports a small series of experiments into the effect of various doses of the *x*-ray upon cell growth. Having soaked a number of beans in water for six hours he treated the different beans with different doses of the rays, and then planted them. His results were quite uniform and demonstrated two points of interest. Whereas those beans which were treated with large doses of the rays were partially or completely inhibited in their growth, as compared to untreated control beans, those which received very small doses were distinctly stimulated; not only were the plants larger and more vigorous, but the flowers were larger and the resulting crop of beans better. From these findings Schmidt suggests that the same phenomenon may apply to animal cells, and experiments which he carried out on an ulcer on the arm suggest that this is the case. If this be so it is evident that in treating conditions in which healing and proliferation are desired, as a sluggish ulcer, very small doses of the *x*-ray should be used, whereas in cases of malignant growth, where tissue destruction is required, large doses are needed, and small doses instead of destroying the neoplasm may do harm rather than good by stimulating it to renewed activity.

Treatment of Fractures by Parathyroid Medication.

Some time ago Gauthier called the attention of physicians to the value of thyroid medication as an aid in obtaining union in fractures that had refused to unite, and this method of treatment was experimented on with variable results, which were not sufficiently good for it to become generally used. Some excellent results had been obtained, but for some reason the method could not always be depended on. In the *Archives Générales de Chirurgie* for April, 1910, Louis Morel says that he has solved the mystery of the irregularity of the

results, by certain experiments which have shown the importance of the secretion of the parathyroid bodies in producing consolidation of bony tissues. In cases of myxedema in which the stature is stunted thyroid medication causes growth in length of the long bones, and increase in size of the skull. But if thyroid material is given too freely serious accidents occur in the nature of cardiac and pulmonary troubles. There is a relation between osteogenesis and the thyroid apparatus, but the parathyroids are more important than the thyroid itself. They have an importance in the metabolism of the metals present in the body, calcium, magnesium, sodium, and potassium. After removal of the parathyroids there are grave symptoms of disassimilation of minerals in the body, and in men and animals who have died of parthyroid tetanus there is a diminished amount of calcium in the brain. Morel studied experimentally the growth of healthy bone and cicatrization of bone under parathyroid treatment in animals. He found that the action of parathyroid medication is as important in the growth of healthy bone as in the healing of fractures. The action in adult animals is not noticeable, while in the young it is marked. All the osteogenetic rôle of the thyroid glands, indeed, seems to be due to the parthyroid tissue.

Education in Breathing.

The normal type of breathing exists in children of both sexes up to the age when the lives of girls and boys begin to differ, and their dress to change. Then, owing to the donning of the corset, the type of respiration in the girl becomes entirely superior, costal or diaphragmatic, while that of her brother remains of the inferior costal type, the normal and desirable one. Maurice Faure, in the *Gazette des Hôpitaux*, for March 31, 1910, brings out these facts in an interesting way. The respiration of the infant begins automatically and goes on in the same way. At the same time respiration may be modified by the will and by education. This is shown by the acquired diaphragmatic respiration of the singer, the man who blows upon a wind instrument, etc. The diaphragmatic type is that of men because they have no constricting waist bands, and their clothing is suspended from the shoulders. It is the type of those who make violent efforts. Because the corset immobilizes the lower part of the thorax the woman's type is the costal. It results from a regression, a degeneration of the normal type. The primary object of respiratory education is to cause the child to preserve its costal respiration and make use of both the diaphragm and the ribs. The secondary object is to maintain the respiratory interval, and expand the chest. It is a mistake to suppose that because a man is an athlete therefore he breathes well. A man may be a good athlete and a bad breather. Respiratory exercises should be taken with the chest bare, and in children a comrade should be used as an example. Singing and blowing may be added to the other exercises. A thorax may appear large and well developed muscularly and yet the person may not breathe well. A permanent increase in the expansion of the chest may be obtained by exercises. All sorts of exercises that develop the movements of the trunk are valuable. Extension and flexion of the trunk, and of the limbs with the body fixed, both in the dorsal position and standing are valuable. Acrobatic gymnastics are useless and may be injurious so far as increasing respiration is concerned. They tetanize the thorax and develop the muscles of the arms rather than those of the thorax. Graduated exercises of the shoulders, trunk, and thorax are indispensable.

The Tubercle Bacillus in the Sputum.

During the past few years workers with tuberculosis and its early diagnosis have become less satisfied with the common method of selecting from the sputum one or two likely looking particles and examining these for the tubercle bacillus, and have sought for methods by which from larger quantities of material the organisms may be isolated in concentrated form. This search has resulted in various methods more or less unsatisfactory. In the *Münchener medizinische Wochenschrift* for April 19, 1910, Zahn of Strassburg reports a new method for which he claims the advantages of simplicity and speed. To from 5 to 15 c.c. of sputum are added 50 c.c. of distilled water and 5 c.c. of a 4 per cent. solution of sodium hydrate. This mixture is shaken in an Erlenmeyer flask, boiled for two or three minutes, and then cooled under the tap. Then one or two c.c. of a 5.5 per cent. solution of calcium chloride is added, and the mixture is again well shaken. The now almost clear fluid is centrifugated for one to two minutes, after which the supernatant fluid is poured off, more material added, and the process repeated several times, when the sediment is collected in the bottom of the two tubes. In the absence of a centrifuge the material, after the addition of the calcium chloride, is well shaken with glass pearls, and is filtered. The sediment from the tubes, or the precipitate upon the filter paper, is now spread upon slides, allowed to dry in the air, and stained by the usual method. The same procedure may be applied to the urine, to ground-up organs, to stools, to exudates, and to blood. When dealing with fluids the sediment obtained on standing is used for the original material. From the author's description the method would appear to be simple and more time saving than many which have recently been offered to solve the problem of finding the occasional needle in the hay stack of the sputum.

News of the Week.

National Confederation of State Medical Examining and Licensing Boards.—The twentieth annual convention of the National Confederation of State Medical Examining and Licensing Boards was held at St. Louis, Mo., during the first week in June, under the presidency of Dr. A. Ravogli. After an invocation by the Rev. Stephen F. Sherman, Jr., Dr. A. H. Hamel, chairman of the local committee of arrangements, introduced Dr. Joseph S. Grindon, who delivered the address of welcome, which was responded to by Dr. Joseph C. Guernsey. Dr. A. Ravogli delivered the annual address of the president, "A Plea for More Practical and Extended Clinical Instruction for Medical Students." The report of the secretary-treasurer, Dr. M. G. Motter, was read, audited, and approved, showing a total of $557.89 with a balance of $228.08. The report of the Executive Council was read by Dr. N. R. Coleman, referred to a committee which commended the subject matter for its practical value to medical educators and recommended the adoption of an amendment to the constitution providing for

a corresponding secretary, and the appointment of a committee to confer with a committee from the American Confederation of Reciprocating, Examining, and Licensing Medical Boards on the feasibility of uniting the two bodies. According to the subsequent report of this committee, the proposed union was found to be impracticable at present. The report of the Committee on Clinical Instruction, by Dr. Henry Beates, and that on Materia Medica, by Dr. M. G. Motter, were read and referred for publication. The Symposium on Clinical Instruction was opened by Dr. George Dock, who said that present school conditions warrant the introduction by the boards of practical examinations, that the material is available, that their purpose should be to test the applicants' methods, and that they would necessitate expert examiners. Dr. Fred C. Zapffe contributed a valuable and timely paper on the "Present Status of Clinical Instruction." Dr. J. C. Guernsey discussed the advantages of the old preceptor system; Dr. J. C. Oliver opposed the lengthening of the medical course to five years; Dr. A. F. Stephens dwelt upon the importance of postgraduate clinical work. With reference to the introduction of practical examinations by the State boards, Dr. Thomas McCrae discussed instruction in clinical medicine, Dr. A. D. Bevan instruction in clinical surgery; Dr. C. F. Hoover, instruction in diseases of the heart and lungs; Dr. W. A. Hardaway, diseases of the skin, and Dr. D. T. Vail, refraction. Dr. J. Coons outlined the methods of practical examinations in histology, pathology, bacteriology, uranalysis, etc. The Board of Medical Examiners of Utah, the State Medical Board of Arkansas Medical Society, the Eclectic State Medical Board of Arkansas, and Drs. E. J. Collins, A. H. Hamel, Frederic Singer, Darlington Snyder, R. O. Tucker, and N. P. Colwell were admitted to membership in the Confederation. The following officers and committees were elected: *President,* Dr. J. C. Guernsey, Philadelphia, Pa.; *First Vice-President,* Dr. James A. Egan, Springfield, Ill.; *Second Vice-President,* Dr. Charles A. Tuttle, New Haven, Conn.; *Secretary-Treasurer,* Dr. George H. Matson, Columbus, Ohio; *Assistant Secretary,* Dr. Darlington Snyder, Columbus, Ohio.

Saner and Safer Fourth.—The *New York Times* reports the casualties of the Fourth of July celebration this year to be 24 dead and 1,294 injured, not counting the man slugged at Reno, Nevada. Last year the deaths were 44 and the injured were 2,361. It's worth while foregoing a little noise to save twenty lives and to prevent more or less acute suffering and disabling injuries of 1,067 persons, chiefly children.

Pollution of New York Harbor.—That the sewage now being emptied into New York Harbor is a menace to the public health is the conclusion reached by the Metropolitan Sewage Commission, which recommends that an interstate board be created by New York and New Jersey to protect the harbor for all time. The commission, which is the successor of the New York Bay Pollution Commission, is composed of George A. Soper, President; James H. Fuertes, H. de B. Parsons, Charles Sooysmith, and Dr. Linsly R. Williams, selected because of their sanitary or engineering experience. Studies carried on in cooperation with the United States and Geodetic Survey have shown that the sewage which is discharged into the harbor is not flushed out to sea, but is assimilated by the water, and the work of the commission has included several thousand chemical and bacteriological analyses to determine the digestive capacity of the harbor waters. The commission finds that there is danger that the assimilative capacity of the water will soon be exhausted, and that intolerable conditions will result from the emptying into the harbor of an excessive amount of sewage. New York Harbor above the Narrows is now unfit for bathing purposes, and the eating of oysters and shellfish from these waters is dangerous. The commission recommends the abolishment of the bathing establishments along the docks of the city. While the cost of keeping all sewage out of the harbor would be prohibitive, the commission finds that great good would be accomplished by removing as much as possible of what is harmful in the sewage, and discharging the remainder under the most favorable circumstances. The commission is strongly opposed to the great trunk sewers which have been proposed to drain the Passaic and Bronx valleys, as these would turn into the harbor immense volumes of sewage from inland towns which should be disposed of in a more modern and sanitary manner.

Hospital Roof Camp.—The New York Throat, Nose, and Lung Hospital on East Fifty-seventh street, has recently opened a camp on the roof of the hospital building for the outdoor treatment of tuberculous patients. The camp is open on three sides and has large ventilating skylights. The dormitory, accommodating ten patients, is in a gallery along the closed side. A dining room, dressing rooms, and shower baths complete the equipment.

Free Bath Season Begins.—July 1st saw the opening of the free bath houses at the Battery. Later on the Board of Education will provide swimming instructors for both boys and girls.

Fire in Nurses' School.—A small fire in the training school connected with Bellevue Hospital, New York, was extinguished without the aid of the fire engines by the attendants of the building. The training school adjoins the new hospital pavilions, C and D, but none of the patients were disturbed by the alarm.

Comfort of Employees.—The New York State Welfare Committee of the National Civic Federation has formed plans for extending its work which was originally designed to promote the comfort and well-being of employees in factories and workshops. A committee of education and suggestion to devise ways and means of increasing the number of attractive and sanitary workshops has been appointed, as well as a committee on the improvement of factory inspection. The committee feels that sufficient laws have already been enacted, and that the enforcement of these will guarantee the safety and comfort of the employees.

The Army Medical School has recently moved from its old quarters in the Army Medical Museum and Library Building in Washington to the new quarters in the large building known formerly as the Builders' Exchange, No. 721 Thirteenth street, Northwest, between G street and New York avenue. The school will occupy five floors of the building, beginning on the second floor, which will have the administrative offices, the lecture hall, and the locker and darkrooms. The chief feature of the floor above, the third story, is the chemical laboratory. On the fourth floor is the bacteriological laboratory. About sixty students can work at once in each of these laboratories. Four days will be

given to bacteriological work and two to chemistry laboratory work. The fifth floor will be given over to Major Frederick F. Russell, who is the expert in typhoid vaccination and allied studies. Here five rooms will be used by him and his assistants and clerks. On the sixth floor is the room to be devoted to operative surgery. On this floor, too, will be the *x*-ray apparatus.

A Medical College for Manchuria.—At the annual United Conference of the missions of Manchuria, held in Newchwang in May, resolutions were unanimously passed strongly urging the establishment of such a college, and heartily recommending it to the liberal support of all interested in the welfare of the Chinese. It will be essentially a missionary institution. Through the generosity of the Chinese, a suitable site for the college has been obtained, contiguous to the hospital, and well situated.

The Medico-Legal Society of Belgium has organized an International Congress of Legal Medicine, to be held in Brussels August 5-10, 1910. The president of the society is Dr. Eugene Dewez, and the general secretary is Dr. Camille Moreau, 6 rue de la Gendarmerie, Charleroi, Brussels.

Harvard University, at its recent commencement exercises, conferred the degree of Doctor of Sciences upon Dr. Theobald Smith of the Harvard Medical School.

A New Institute for Medical Research.—Announcement has been made of the establishment of the Otho S. A. Sprague Memorial Institute for the Scientific Investigation of the Causes of Disease in Chicago, with an immediate endowment of $1,000,000. Provision for establishing the institute was made in the will of O. S. A. Sprague, a Chicago merchant, who died last year.

Rockefeller Institute Appointments.—The Board of Directors of the Rockefeller Institute for Medical Research announce the following promotions and appointments for the year 1910-1911: Laboratory Staff—Member: Jacques Loeb, experimental biology. Associates: W. A. Jacobs, biological chemistry; D. R. Joseph, physiology and pharmacology; Peyton Rous, pathology; B. T. Terry, protozoology; D. D. Van Slyke, biological chemistry. Assistants: M. T. Burrows, experimental surgery; P. F. Clark, bacteriology; I. S. Kleiner, physiology and pharmacology; Hardolph Wasteneys, experimental biology. Fellows: F. J. Birchard, biological chemistry; F. B. La Forge, biological chemistry. Scholar: J. Bronfenbrenner, pathology. Hospital staff: G. Canby Robinson, George Draper, H. K. Marks, F. W. Peabody, H. F. Swift. General manager: Jerome D. Greene.

Charitable Bequests.—By the will of the late Elizabeth C. Burkhart of Philadelphia the sum of $3,000 is bequeathed to the Philadelphia Home for Incurables and $3,000 to the Hahnemann Medical College and Hospital.

The Floating Hospital of St. John's Guild in New York made its first trip for 1910 on July 5. In the summer of 1909 the Floating Hospital carried 11,155 women, and 27,895 children. The total number of women and children carried since the work of the guild was begun is 1,337,602.

The Phipps Institute.—The University of Pennsylvania is preparing to carry on the work of the Henry Phipps Institute for the Study, Prevention, and Treatment of Tuberculosis, for which Mr. Phipps already has provided more than $5,000,000. Ground has been acquired in Philadelphia for a hospital, and the donor and the trustees have approved the report of a committee appointed to outline the policy of the institute. There will be three general departments, each with a director. Dr. Paul Lewis of the Rockefeller Institute for Medical Research will be director of the laboratory. Alexander M. Wilson of the Boston Association for the Relief and Control of Tuberculosis will be in charge of the sociological, and Dr. H. R. M. Landis of the clinical department. There will be a board of eight directors, and in addition an advisory council has been created, which will meet once a year. The following have accepted membership in the council: Dr. Samuel G. Dixon of Harrisburg, Pa.; Dr. S. McC. Lindsay of New York; Dr. William H. Baldwin of Washington, D. C.; Dr. Herman M. Biggs, New York; Dr. William H. Welch of Baltimore, Dr. Theobald Smith of Boston, Dr. Gideon Wells of Chicago, Dr. Simon Flexner and Dr. James A. Miller of New York, Dr. Laurison Brown of Saranac, N. Y.; Dr. Henry Baird Favell of Chicago, and Dr. James Pratt of Boston.

The Mott Memorial Medical and Surgical Library, established in 1867, has been presented to the library of the New York Academy of Medicine.

University of Vermont.—Thirty graduates of the medical department of the University of Vermont received the degree of Doctor of Medicine at the 106th commencement on June 29. Large gifts to the university have made it possible to secure the $100,000 offered conditionally by the General Educational Board, so that the endowment fund now amounts to a half million dollars.

Red Cross Mine Work.—The American National Red Cross plans to introduce in the bituminous mining districts the first aid to the injured system which has been in use for several years in Pennsylvania. The Pullman Car Company has donated a car in which visits will be made to the mines throughout the country, and instruction will be given to employers and employees in the most approved first-aid methods. The railroads over which the car will travel have, with the sanction of the Interstate Commerce Commission, agreed to furnish free transportation, and it is expected that the work will be begun during the latter part of the month under the supervision of Dr. M. J. Shields.

Addition to Hospital.—Through the munificence of Thomas Bradley, president of the Methodist Hospital of Philadelphia, a four-story addition will be made to the hospital at a cost of $41,000. It will contain diet kitchens, dining room, serving room, chief resident physician's suite of rooms, officers' dining rooms, general dining room, and bed rooms for employes. The new building will afford accommodations in the hospital for fifty additional patients.

The Manitoba Sanatorium for Consumptives was formally opened near Ninette on June 22, 1910. The institution as it now stands cost $65,000 and will when fully equipped accommodate 80 patients.

The San Antonio (Tex.) Free Dispensary and Hospital was dedicated on June 23, 1910, the new building on South Laredo street, San Antonio, having been completed.

The Wisconsin State Medical Society, at a meeting held at Milwaukee June 23, elected the following officers: *President,* Dr. Hiram Caples of

Waukesha; *Secretary,* Dr. C. S. Sheldon of Madison; *Treasurer,* Dr. Sidney R. Hall of Ripon.

The Des Moines Valley Medical Association held its thirty-ninth annual meeting at Ottumwa, Ia., June 23, 1910. The following officers were elected: *President,* Dr. L. W. Littig of Iowa City; *Vice-Presidents,* Dr. L. A. Rodgers of Oskaloosa and Dr. D. C. McClure of Bussey; *Secretary-Treasurer,* Dr. Fred Bowles of Ottumwa. *Censors,* Drs. S. A. Shillman of Ottumwa, J. A. Replogle of Udell, and H. C. Young of Bloomfield.

The Orleans County (Vt.) Medical Society met at Barton recently and elected the following officers: *President,* Dr. R. M. Wells of Orleans; *Vice-President,* Dr. C. C. Waller of North Troy; *Secretary and Treasurer,* Dr. J. C. Colby of Derby Line.

The American Association of Clinical Surgeons is at present in London, England, visiting the clinics of that city, the members being the guests of the London Surgical Society. Thirty members of the association are on the trip.

Mr. Henry C. Weeks, known as the foe of the mosquito and the friend of the shade tree, died recently at his home in Bayside, L. I. Mr. Weeks was the first secretary of the American Society for the Extermination of Mosquitos, and was an active experimenter in carrying on the fight, the present general public interest being largely due to his efforts.

Obituary Notes.—Dr. Henry Harris Aubrey Beach of Boston, Mass., died on June 28, 1910, aged 66 years. He was a graduate of the Harvard Medical School in 1868. Dr. Beach has served as assistant and demonstrator in anatomy and instructor and lecturer in surgery in the Harvard Medical School, and at the time of his death was consulting surgeon to the Massachusetts General Hospital. He had been an associate editor of the *Boston Medical and Surgical Journal,* was president of the Boylston Medical Society in the early seventies, and belonged to the American Medical Association, American Social Science Association, Massachusetts Medical Society, Boston Society for Medical Improvement, Boston Society of Medical Sciences, the American Association for the Advancement of Science, and the Biological Society of Washington, D. C.

Dr. George P. Yost of Glen Rock, Pa., died at Baltimore on June 12 at the age of 62 years. He was graduated from the Washington University School of Medicine of Baltimore in the class of 1871.

Dr. Ephraim S. Wynn died suddenly of heart disease at Camden, N. J., on June 13, at the age of 61 years. He was graduated from Jefferson Medical College in the class of 1872. He was secretary of the Medical Board of the Fidelity Mutual Life Insurance Company of Philadelphia.

Dr. Henry S. Warren of Boston died at his home June 25, 1910, aged 37 years. He was a graduate of the Harvard Medical School in 1900. Dr. Warren was at one time house physician to the Children's Hospital in Boston, and later was one of the physicians in charge of the Harvard football team. He was a member of the Suffolk District Medical Society, the Massachusetts Medical Society, and the American Medical Association.

Dr. Eugene T. Wilhelm died at South Bethlehem, Pa., on June 24 at the age of 61 years. He was graduated from Jefferson Medical College in the class of 1878. He was president of the Local Board of Health.

Dr. Albert O. Bogert of Spring Valley, N. Y., died at his home June 24, 1910, aged 58 years. He was a graduate of the College of Physicians and Surgeons of New York in 1875 and a member of the Erie County Medical Society, and the Medical Society of the State of New York.

Dr. John F. Bennett of Detroit, Mich., died suddenly in Northfield, June 19, 1910, aged 46 years. He was a graduate of the Detroit College of Medicine in 1892 and was a member of the Wayne County Medical Society, the Michigan State Medical Society, and the American Medical Association. Dr. Bennett was coroner of Wayne County.

Dr. Jacob Wesley Berton of Providence, R. I., died in the Boston City Hospital June 20, 1910, aged 65 years. He was a graduate of the New York University Medical College in 1878 and had practised in New York City, Trenton, N. J., and Providence, R. I. He retired from practice six years ago.

Dr. William Lobdell Johnson of Johnstown, N. Y., died at his home, June 26, 1910. He was a graduate of the Albany Medical School in 1865, and was a member of the Fulton County Medical Society, and the Medical Society of the State of New York. Dr. Johnson was the third of his name to have been prominent in medical affairs of Fulton County, his father and grandfather having practised in Johnstown before him.

Dr. W. J. Lewis of Hillsboro, N. B., died at his home June 23, 1910, aged 80 years. He was graduated from the University of Glasgow in 1855, and the same year received the degrees of L. R. C. S. and L. R. C. P. Edin. Dr. Lewis took a prominent interest in political affairs, having sat in the House of Commons for two terms.

Dr. J. Winthrop Spooner of Hingham, Mass., died at his home, June 19, 1910, aged 64 years. He was a graduate of Harvard University in 1867, and of the Harvard Medical School in 1871. For 24 years he was medical examiner for Plymouth County. Dr. Spooner was an ex-president of the Norfolk District Medical Society, and a member of the Massachusetts Medical Society, and the American Medical Association. He was also an ex-president of the Medico-Legal Society.

Dr. Belle Walrath of St. Paul, Minn., died at St. Luke's Hospital, June 20, 1910, aged 63 years. She was a graduate of the Northwestern University Woman's Medical College in 1882, and was a member of the Ramsey County Medical Society, the Minnesota Medical Association, and the American Medical Association.

Dr. Alfred Willard Southgate of Worcester, Mass., died at the Worcester City Hospital June 25, 1910, aged 31 years. He was a graduate of Amherst College in 1901 and the Harvard Medical School in 1906, and was a member of the visiting staff of the Worcester City Hospital.

Dr. Charles Zellhoefer of Brooklyn, N. Y., died at his home June 29, 1910, aged 65 years. He was a graduate of the New York University Medical College in 1873, a consulting physician to the Eastern District and German Hospitals of Brooklyn, and a member of the Medical Society of the County of Kings and the Medical Society of the State of New York.

Dr. Richard Joseph Nunn of Savannah, Ga., a well-known Mason and a veteran of the Confederate Army, died at his home on June 29, aged 79 years. He was graduated from the Savannah Medical College in 1854, and was active in the fight against yellow fever in the South.

Correspondence.

DEATHS RESULTING FROM THE ADMINISTRATION OF ANESTHETICS.

To the Editor of the Medical Record:

Sir:—On Dec. 15, 1908, a committee of experts was appointed in England "to inquire into the law relating to coroners and coroners' inquests, and into the practice in coroners' courts." By the special instruction of the Secretary of State, the committee was asked to investigate the question of deaths resulting from the administration of anesthetics. The so-called coroners' committee, therefore, made a thorough inquiry into the whole subject of anesthetics, in the course of which many expert witnesses were examined and considerable data bearing upon the various phases of the subject were collected. The results of the inquiry have recently been made public in a parliamentary report,* dated March 18, 1910.

It was brought out that the number of deaths reported in the United Kingdom as having been caused by anesthetics had increased quite rapidly and considerably in recent years. In the single year of 1908 no less than 235 fatalities from anesthetics were reported to the coroners of the United Kingdom. The available statistics, however, were found to be unsatisfactory both because of incompleteness and because of imperfections in the returns. For example, in many cases the statistics did not clearly indicate whether the deaths were from an anesthetic or under an anesthetic. Obviously, a death under an anesthetic might have been due to the shock of operation or to an accident incident to the administration of the anesthetic—such as asphyxia, resulting from the tongue slipping back, or regurgitation of food. To determine the relative hazards of the various anesthetics as administered under varying conditions, the statistics of fatalities must clearly discriminate between the deaths which should be charged to the drugs, or deaths from anesthetics, and deaths under anesthetics, and the latter should discriminate so far as possible between the deaths due to shock of operation and deaths due to the effects of the anesthetic. At best, the line of demarcation cannot always be sharply drawn.

The committee, after a careful examination into all the available facts, came to the conclusion that "when all sources of error are allowed for, we have the fact that there is an increasing number of deaths under anesthetics, and that in the opinion of experts a certain number of these deaths are due to preventable causes." They further agreed that "a certain number of deaths are inevitable whatever the care and skill may be with which the anesthetic is administered."

The report in its entirety should be of interest to all surgeons, practitioners and dentists who make any use of anesthetics. The more important recommendations of the committee are as follows:

"(1) Every death under an anesthetic should be reported to the coroner, who, after inquiry, should determine whether it is desirable to hold an inquest or not. (2) In the case of every death under an anesthetic the medical certificate of death should specify the fact whether the anesthetic was the actual cause of death or not. (3) No general respirable anesthetic should be administered by any person who is not a registered medical or dental practitioner. (4) Registered dentists should be confined to the use of nitrous oxide gas for dental operations, and should not employ the general respirable anesthetics of longer duration. (5) Intraspinal anesthesia should be practiced only by registered medical practitioners. (6) Practical and theoretical instruction in the administration of anesthetics should be an essential part of the medical curriculum. (7) Such instruction in the administration of nitrous oxide gas should be an essential part of the dental curriculum. (8) In the case of any death under an anesthetic in a hospital or other similar public institution, there should be a scientific investigation into the actual cause of death, conducted by the authorities of the institution. (9) A small standing scientific committee on anesthetics should be instituted under the authority of the home office."

Inasmuch as there is likely to be a continued and rapid progress in surgery in the United States as well as in England, with an increasing number of patients submitting to operations in which anesthesia is desirable or necessary, it is quite probable that most, if not all, of the conclusions and recommendations of the English Coroners' Committee are equally applicable to this country.

Frederick S. Crum.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HOSPITAL SUNDAY—MALTA FEVER—ACUTE HEMORRHAGIC PANCREATITIS—NATIONAL SOCIETY FOR THE PREVENTION OF CONSUMPTION—SIR T. BARLOW—SANATORIUM SOCIETY—TERRITORIAL SANITARY SERVICE—OBITUARIES.

London, June 17, 1910.

Hospital Sunday opened the week, and the usual collections were made. It is not known at present whether the response will prove an advance, as the amounts have not yet been returned. But from one or two churches I have heard of collections of sums above the average, so it may be hoped the fund will not be found to have diminished.

In the House of Commons a member, who appears to have a difficulty in dealing with statistics, wanted to know what was the good of further research as to Malta fever, and objected to public money being spent in this way, when the fever had practically been extinguished in the British troops. He was informed from the ministerial bench that Sir David Bruce had informed the commission quoted that goats were capable of infecting man when they themselves remained healthy. The prohibition of the use of goats' milk in the barracks had been most successful. In July, 1906, it was issued, there having been 123 soldiers admitted to the hospital up to that period of that year; in the remaining months there were only 40. In 1907 there were 11; in 1908, 5; the next year only one, and during the present year up to date, none. Among the civil population it is hardly practicable to prohibit the use of the milk of goats. Research into the causes of the infection in these animals is therefore most desirable in order if possible to remove them.

Acute hemorrhagic pancreatitis is met with occasionally, and may be mistaken for some other abdominal lesion unless the case is carefully examined. Perhaps it is more common, as usually taught, in adult males who are rather fat and indulge freely in alcohol; but such is not always the sort of patient. Two cases were related by Dr. A. Elliot at the West London Society on the 3d inst., and formed the basis of a paper on the subject. They were in men of 40 and 50 years respectively, addicted to alcohol. The diagnosis was suggested by extreme suddenness and severity of the pain, with persistent and urgent vomiting—this symptom-complex being more frequently found, said the author, than in other acute abdominal attacks likely to be taken for it. There was not much tenderness on palpation in the early symptoms of either case; and collapse, which some writers have insisted on, did not occur until late. Dr. Elliot recommended early surgical intervention. Mr. McAdam Eccles said drainage through the lesser omentum with free drainage of the biliary passages gave the only chance to the patient, and then only if done early. Dr. G. C. Low described four autopsies he had made and said fat necrosis was only found in the abdominal cavity. In a malarial case he had not found any fat necrosis. Dr. Cairns Forsyth had seen six cases operated on, but only one of them was successful. He thought many cases might not be inflammatory at first, but rather a pancreatic apoplexy. They were generally seen in patients in whom other hemorrhages seemed likely to occur. He suggested placing a gauze drain in the foramen of Winslow, if patent, as well as the drainage others had advised.

The National Association for Prevention of Consumption is appealing for funds to carry out its educational campaign by (a) traveling exhibitions, (b) caravans with lantern slides for small towns, (c) popular lectures, (d) information bureau for press and public, (e) distribution of literature. It is urged that success in the war against the disease depends on the cooperation of all classes. It is pointed out that £500 will fit out a traveling exhibition and £600 will run it for a year; £300 will fit out a caravan and £700 run it for a year; £5 will pay for a lecture; £1 for a set of slides, and one penny for some leaflets.

On the 8th new buildings were opened on a ridge of the Chilterns erected by the National Children's Home and Orphanage Committee when addresses were delivered by medical and other supporters. Sir T. Barlow, F.R.C.P., passed in review the advances made in the treatment of consumption, and laid down some preventive principles. He gave primary importance to the feeding of children with varied diet—pure milk and butter, bacon—which, he said, had virtues not commonly recognized—well cooked vegetables. A diet of this kind he recommended for children. People should give up sending flowers to hospitals, superseding them by gifts of fruits and fresh vegetables. Well-cooked fresh meat was another necessity.

The Royal National Sanatorium's annual meeting of governors has also been held this week, and the 55th report adopted. The balance sheet once more shows a considerable deficit. During the year 502 patients were treated. The most important business was a question of extension of the work. They were faced with a proposal to adopt the system of graduated labor, which was thoroughly advocated by their medical advisers. This was impossible, the committee reported, with their present grounds, which did not exceed three acres. Land would be required on which patients could be set to agricultural labor, and workshops for indoor employment. It was estimated that £30,000 would be necessary to secure a sufficiently commodious site and erect a new sanatorium. A hope was expressed that land might be presented, or at least offered at, a very low price. The meeting decided to ask the committee to prepare a scheme and submit it to the next meeting.

Livingstone College, named after the great medical missionary, is devoted to the training of missionaries so far as to be of service to their brethren during illness and to the communities where they labor. They do not call themselves medical missionaries, but endeavor to be of service where qualified doctors are not available. At Commemoration Day last week, Dr. Harford, principal, read extracts from an address by Professor Ronald Ross, who indicated the success of the anti-malarial campaign and the assistance the college could enable the students to give. Dr. J. H. Cook, who had worked many years in Uganda, said the students of the college had been able to give valuable work, and it would be well for a much larger number of missionaries to be trained in the college before going abroad.

Lt. Col. C. H. Melville, Professor of Hygiene at the R. A. M. C., gave an address on the 8th before the Sanitary Institute on the work of the sanitary service of the new territorial force. He told the officers their first duty was to maintain the resisting powers of the soldier, by attending to the water supply and camp conservancy as well as a study of food, clothing, work and play, in all of which tact was necessary. Their force differed from the regular army, as it had no continuous existence as an organized body in times of peace. So whatever breathing time the force might have when called out, none whatever would be allowed to the sanitary department. They would not get six weeks nor even six days to prepare. From the first moment of mobilization, sanitary work would begin, and if they had not learned it during peace, the price would be so many territorials in the hospital and so many in the grave. Before the army men saw an enemy it would, he calculated, in such a case, suffer a loss equal to that which a severe engagement might inflict. Their duty, therefore, was to study in time of peace the conditions they would have to face in war.

Many members of the profession attended the service at Nottingham in memory of Dr. Arthur J. Sharp, who has died at the age of 42, after a protracted illness, the result of septicemia contracted, it is thought, in the performance of a post mortem. The funeral was at Ambleside, the service at Nottingham taking place simultaneously.

Surgeon-General J. G. Faught, K.H.S., died on the 12th inst. in his 78th year. He joined the army service as assistant-surgeon in 1855 and was employed as sanitary officer at Cape Coast Castle during the Ashanti War of 1874 and served in the Afghan War, 1878-80, receiving a medal in each case. Again he saw service in the Egyptian War, 1882, in Bechuanaland, 1884-5, as P.M.O. to Sir C. Warren's expedition, and finally in the campaign against the Zulus in 1888.

Dr. T. E. Smith, of Trinity College, Dublin, died on the 8th inst. after an operation for appendicitis, aged 47.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

CHLOROFORM ACCIDENTS IN THE ICTERIC—TREATMENT OF ANGIOMATA WITH HOT AIR—EXPERIMENTAL POLYURIA—GENERAL TREATMENT OF SURGICAL TUBERCULOSIS OUTSIDE OF CITIES.

PARIS, June 15, 1910.

THE rôle of anesthetics in the pathogeny of accidents after operation on hepatic patients is considerable. While chloroform causes serious accidents, ether, on the contrary, produces very simple operative results. Without denying that ether also may have injurious action on the kidneys and the liver, that injurious action is infinitely less than that of chloroform. It results from this, according to Quénu, that ether should be used in all operations on the icteric, while in such patients the use of chloroform is absolutely to be condemned. Jean Louis Faure shares this same opinion, and thinks that among the icteric all post-operative accidents are to be attributed to the action of chloroform. Chaput thinks that we should prefer lumbar anesthesia to chloroform or either. Lucas-Championnière and Régnier think that if the injurious action of chloroform on the liver is sometimes noted it is only in exceptional circumstances, and in livers whose resistance has been reduced. Sieur thinks that in true hepatics chloroform presents dangers, and that its use should be especially avoided in alcoholics whose livers are always diseased.

Ricard presented three patients who had angiomata of the face, which had been treated with hot air. The especially interesting facts in this treatment are the very great rapidity of cure and the perfection of the cicatrix. Broca thinks that this treatment of angiomata by means of hot air should not be applicable only to those on the surface, but that by removing the eschar as fast as it forms excellent results may be obtained in growths as large as a nut. He thinks this treatment superior to electrolysis, and that the eschar obtained by hot air is very superior to that obtained by the galvanocautery. Vasquez and Cottet have studied experimental polyuria. The urinary secretion is not continuous, but presents variations following a rhythm which is not the same in the normal as in the pathological condition. The urine secreted during the day is more abundant and less dense than that secreted during the night. We must take account in diuresis of extrarenal factors which are numerous and varied; we must take account of the apparatus of absorption and of circulation (stomach, liver and heart); we must also take into account the effect of the nervous system, the intervention of which explains certain bizarre kinds of rhythm, but which in practice may be neglected. The urinary secretion depends not solely on the functional condition of the kidney, but on the quantity of materials which the blood brings in a given time. If we cannot act upon the functional condition of the kidney, we may experimentally modify the blood current, for we may very simply cause variations in the circulation of liquids in the organism by change of attitude. In fact, the upright position with relation to the horizontal position presents an obstacle to the normal progress of liquids by the simple fact of the intervention of the law of gravity. The notion of renal permeability shows how important it is to take notice of the amount drunk, not only its quality, but also its quantity, which should be regulated by the renal needs. In the normal condition, when the kidneys and the heart are healthy, the ingestion of a large amount of water presents no inconveniences, because it is eliminated as soon as it is absorbed; but when the kidneys are diseased and are no longer able to eliminate the water in proportion to its penetration into the circulatory stream, it increases the mass of the blood and the work of the heart, which suffers the more as it is more diseased. From this is deduced the already long known indication to reduce the amount of liquids in cardiac and Bright's disease. Courtellemont had seen cases in which the ingestion of 600 to 1,000 grams of water were sufficient to precipitate vomiting, headache, palpitation, vertigo, and even pulmonary edema. As conclusion, it is necessary in treatment of diuresis in the great majority of cases to enjoin the horizontal position, ordering them not to drink in that position, and to keep this position for a variable time according to the case. Under the influence of the horizontal position patients get a better diuresis, while dyspeptics, cardiacs, and those fatigued benefit by repose in the

horizontal position in various ways. In treatment of diuresis we should take into account the condition of permeability of the kidneys; and on the other hand expect that it will differ greatly according as it is proposed to act on the general equilibrium of the economy, or to produce in the urinary apparatus a lavage by the passage of a veritable water race. Under pain of grave misconception the ingestion of water should be dosed according to the eliminative power of the kidneys. Paul Delbet thinks that tuberculosis cases are not cured any more easily at the seaside or in the country than in the city. To obtain a cure in surgical tuberculosis there is needed good hygiene, a well regulated life without excessive fatigue, good nourishment, air, and sunshine. If these conditions can be obtained in cities it is preferable that the patients be treated there. Tuberculosis patients may be treated anywhere provided that they may have good hygiene and be properly cared for. Instead of constructing distant and costly sanatoria it would be better to construct in cities habitations for workmen that are healthy and full of fresh air and light. Judet thinks that it is possible to cure in cities surgical tuberculosis with good hygiene and good local treatment. Lance thinks that surgical tuberculosis is more easily cured at the seashore or in the country than in the city. The pure air, the wind by its continuous action, are stimulants of the exchanges, of assimilation, and of appeite. The action of solar light is particularly remarkable. Sunburn is a sign of great importance, and it is to be noted that those who do not present it obtain much less benefit than others from a sojourn at the seaside. Brodier thinks that sea baths, sea air, sun, altitude, are precious auxiliaries in surgical treatment. The change of surroundings gives the organism an excellent stimulus, but in the country, the mountains, at the seaside the most valuable results of treatment are not obtained unless the patients enjoy themselves. Mayet thinks that for the formulas above given we should substitute the following: Bony tuberculosis may be cured anywhere when it is properly treated. The importance of outdoor air is considerable, and the principle of the open window should be widely accepted. A very interesting experiment has been made by Lannelougue and Achard; they took several parcels of guinea pigs of the same age and as far as possible the same weight, and the same day inoculated them in the peritoneal cavity with the same amount of the same culture of tubercle bacilli. Then these different parcels of animals were placed in different hygienic climatic conditions: The country, the seashore, the coast of La Mancha, high altitudes, the South, the North: the last lot was kept in the laboratory in a dark room, but with a window constantly open. The guinea pigs of each lot received daily the same food; whenever a pig died he was sent to the laboratory of Lannelongue for an autopsy. Those that resisted to the last were those in the laboratory. They were not in pure air,but they were always in the air. La Fur thinks that a sojourn at the seashore should be prescribed for tuberculosis of the genitals and urinary organs. Genouville concedes that if genital tuberculosis is treated with advantage at the seaside, it is not so with urinary tuberculosis. Ozenne thinks that if a surgical tuberculosis when well treated locally may be cured in the city as easily as at the seashore or in the mountains, the best observation has shown that there is a considerable benefit from seashore treatment, rural life and high altitudes on the organism afflicted with tuberculosis.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 23, 1910.

Arthrodesis and Its Application in Infantile Paralysis of the Foot.—W. B. Macausland and B. E. Wood report 13 cases of arthrodesis, which is an operation to stiffen joints not completely or at all under the control of normal muscular groups: in consequence of this lack of control deformities develop. Probably the best time to operate is between the eighth and twelfth year. The patient is prepared in the usual manner from toe to knee, inclusive. A tourniquet is advisable. A semicircular skin incision is made between the prominence of the external malleolus and the Achilles tendon, passing one-half inch below this malleolus, forward to a corresponding distance in front of the same, making an incision of from about four and one-half to five inches. This skin flap is then dissected upward. The extensors of the little toes are then pulled forward and the peroneal tendons pulled backward. A similar incision is then made through the ligamentous and capsular covering of the ankle joint, exposing the tibial astragaloid joint. The foot should then be inwardly dislocated. Too great force may injure the tibia. After the joint is thus dislocated the ends of the tibia, fibula and astragalus can then be denuded of cartilage. Other joints may require similar treatment when they are involved in the loss of muscular and ligamentous control. The dislocation is then reduced, bringing the denuded surfaces together. The new approximation is wobbly, and must be made firm in order to secure a good result. To accomplish this, the fibula is fractured by subcutaneous osteotomy and pressed in closely in the application of the plaster. One of the writers has felt that the tibia and fibula should be left in normal relation, so he splits the astragalus in two longitudinally, hoping thereby to secure perfect approximation between the tips of the tibia and fibula, and also to produce excessive callous formation.

The Effect of Tobacco on the Ear and Upper Respiratory Tract.—H. O. Reik offers the following conclusions: (1) It does not appear, at least it has not been proven, that tobacco causes any definite characteristic lesions of the nose, ear or throat. (2) While it is possible that the excessive use of tobacco may by indirect action produce a toxic effect upon the auditory and olfactory nerves, with resulting impairment of the sense of hearing or smell, there is not at present any definite laboratory proof for such an opinion, nor is there sufficient clinical evidence to substantiate the belief. (3) The ill effects of tobacco smoke on existing diseases of the throat arising from other causes are established and are the same as would be observed from any other form of irritation. (4) Gastric and systemic nervous disturbances may arise from excessive use of tobacco in any of its forms. The nicotine content of tobacco is a recognized poisonous substance and in the process of smoking there are evolved other poisonous products. (5). Carbon monoxide is probably a more dangerous and injurious constituent of tobacco smoke than is nicotine, only a very fractional amount of which ever enters the tissues. (6) The cigarette is more injurious than the cigar in that it involves inhaling the smoke, but without inhalation it is no more dangerous than any other form of cigar smoking or pipe smoking; probably not as much so unless enormous numbers are consumed.

New York Medical Journal, June 25, 1910.

Etiology and Symptomatology of Infantile Scurvy.—This question is considered by J. P. Crozer Griffith, who says that there is in addition to dietetic faults an individual predisposition, active in the production of scurvy; otherwise we should find much more of the disease than we do. In some families the disease comes on about a certain age. The most striking symptom is pain, often of sudden onset. The mistaken diagnosis of trauma may be made. Pseudoparalysis is a natural consequence of pain on movement. Involvement of the gums is present in the majority of cases. Swelling of the limbs is another sympton seen regularly in severe cases. Hemorrhage such as occurs beneath the periosteum and in the gums is also seen in other parts of the body, and is most characteristic. It may sometimes occur in the posterior part of the orbit producing exophthalmos and ecchymosis of the eyelids. It is seen also in the form of petechiæ and may occur from the bowel. One of the most frequent forms is, in the author's opinion, from the kidneys. In severe and long continued cases a progressive anemia and cachexia develop. The expression is one of constant pain. The child may sleep but little on account of the suffering. Edema of the parts involved is often very decided, sometimes with a marantic edema of other parts. Fever may be present in moderate amount, appetite is diminished, diarrhea not uncommon; or there may be constipation. Without treatment there is but little tendency to recover.

Pathology of Infantile Scurvy.—C. A. Fife says that recent years have added but little information to our knowledge of the pathological changes in scurvy. The gross lesions are due to increased vascularity and more directly to hemorrhages in the various structures, especially the periosteum, bones and muscles. The subperiosteal hemorrhages occur in preference in the long bones of the lower extremities, particularly the lower ends of the femora. These hemorrhages may be slight or may almost separate the periosteum from the bone. Hemorrhages occur also in the soft and reddened marrow, producing clots around which softening occurs. As a result of this the cancellous portions are absorbed and rarefied and the compact parts greatly thinned. Others maintain

that the bone changes are a cause rather than a result of the hemorrhages. The gums are swollen, congested, bleeding, spongy, and ulcerated. Visceral changes are not important and are due simply to hemorrhages and anemia. Bleeding may occur from any mucosa; extravasations have been found in practically every organ, and may take place in any serous cavity, and on the surface of any serous membrane. The kidney may be the seat of hemorrhage without undergoing any inflammatory change. Albumin, casts, and blood found under these circumstances do not indicate true hemorrhagic nephritis. The blood condition is essentially one of chlorotic anemia. Nucleated red cells, poikilocytes, macroblasts, microblasts, polychrome basophiles in the nucleated reds have all been seen. Recent work seems to indicate that the marrow changes are the basic pathological processes in the disease. The lymphoid marrow becomes poor in cells and in blood vessels, is rarefied and converted into friable scaffold-like tissue resembling embryonal connective tissue which contain spindle cells and a few osteoblasts.

Treatment of Infantile Scurvy.—M. Ostheimer sums up the treatment in a single word, orange-juice. It is as prompt as mercury in syphilis or quinine in malaria. Drugs are probably without value. Much difference of opinion exists as to feeding during treatment. Some stop all proprietary foods, condensed milk or sterilized milk, and substitute either uncooked milk or milk which is boiled just before it is given to the child. The orange juice may be given in doses of one tablespoonful or more every two hours. Grape juice comes next, while lemon juice is regarded unfavorably on account of its great acidity. It has been found that in nurslings, giving orange juice to the mother benefited the child; but it is better to give it directly to the child. The latter needs rest and should be handled as little as possible. Fresh air and plenty of water are naturally of benefit. Beet juice seems to have a doubtful value. Sodium lactate has been advised by Wright of opsonic fame. Iron, arsenic, and cod liver oil may be given late in the disease to infants in whom there is marked secondary anemia or exhaustion. The author thinks that it would be well as a prophylactic measure to give orange juice to all infants who come under our care after having been on any of the proprietary foods, condensed milks or sterilized milks for any length of time. Such infants ought to be at once placed on an uncooked milk mixture. Recovery with the orange juice generally ensues in three or four days.

The Lancet, June 18, 1910.

Influenzal Meningitis.—F. E. Batten reports five cases, one recovering. The diagnosis must rest on the result of bacteriological examination, for this form of meningitis has no features which distinguish it clinically from other forms of the same disease. Routine cultures of the cerebrospinal fluid must be made on some blood medium. A certain suggestive value obtains in the occasional viscidity of the cerebrospinal fluid, but one would be loath to make a diagnosis on this feature alone. Lumbar puncture has been performed in most of the recorded cases, but it can hardly be considered a therapeutic measure; although recovery has followed in some of the cases in which it was done. In the author's favorable case, as soon as the nature of the disease was recognized, urotropin was given in 10-grain doses every four hours for three weeks. It has been noted that after the use of urotropin within therapeutic limits a sufficient amount of the drug appears in the cerebrospinal fluid to exercise a decided inhibitory effect on the growth of organisms, and will markedly defer, and, in some cases, even prevent the onset of a fatal meningitis. The favorable result in the author's case cannot be attributed, he says, to the urotropin; but the fact that all other cases in children under two years of age have proved fatal while this one recovered is suggestive and justifies a further trial of the remedy.

A Note on the Treatment of the Partially Drowned.—J. A. Barnes says that drowning appears to be due, (1), to mechanical asphyxiation and, (2), to shock from sudden and prolonged immersion. He calls special attention to the latter form. The usual directions are, he says, to perform artificial respiration and apply warmth. But, if we look on these cases as due chiefly to shock, something more can be done. The blood is stagnating in the splanchnic areas and we should drive it thence so that the brain may receive its proper supply. He aims at autotransfusion in the following manner. Having started an assistant on artificial respiration he firmly bandages the legs from the feet upwards. A roller towel is then passed round the patient's abdomen, the two ends crossing in front. One assistant is told off to each of these ends. As the arms are brought down to the chest in the expiratory movement of artificial expiration (Silvester's method) these two assistants, grasping the towel-ends firmly with their right hands, pull them; at the same time making pressure on the abdomen with their left hands. In this way considerable squeezing of the abdomen is obtained. As the inspiratory movement commences the pressure is relaxed so as not to interfere with the expansion of the lungs. The process is continued synchronously with the movements of artificial respiration. His idea is that this acts beneficially in two ways: (1) it assists, by pressing up the diaphragm, to more completely empty the chest with expiration; and (2) it squeezes some of the excess of blood from the abdominal cavity. The bandaging of the legs and arrangement of the towel can be very quickly carried out with assistance, of which there is usually no lack in these cases. Gravity should also be made to assist the flow of blood to the brain by keeping the head at a lower level than the body. He gives a hypodermic injection of ether (30 minims) and usually one of strychnine as well. The objection to the use of these stimulants—that they stimulate an already tired center and are quickly followed by increased depression—seems hardly to apply in cases of drowning; for when once reaction has set in recovery is usually rapid. Adrenalin chloride given hypodermically (30 minims of a 1 in 1,000 solution) should act beneficially by raising the blood pressure.

Comparison Made Between the Simple Gastrocirculatory Seizure and the Angina Pectoris Attack.—W. Verdon discusses these two conditions. He contends that the angina seizure is a gastric reflex, that it is evolved from the painless type of gastrocirculatory seizure and that the entity pain is not an essential content of the syndrome but an excrescent appendage. Space does not allow the following out of the argument in all its details. He says that in the anginoid attack there is much else worthy of consideration than the pain. When the attack is considered in regard to its place among the paroxysmal seizures it is found to resemble a class associated with functional disorders of the stomach of which the simple gastrocirculatory seizure known as a vomiting attack is a strong example. The dual syndrome of this latter attack represents a series of operations organized for the purpose of protecting the stomach from the effects resulting from the intrusion of a noxious body. The gastric group of operations have for their object neutralization of the offensive properties of the irritant and its ejection from the gastric cavity; the circulatory group the defense of the gastric wall tissue and the repair of its lesions. When the anginoid seizure is stripped of its pain the remaining symptoms are circulatory and gastric. If the syndrome of the gastric and circulatory symptoms of the anginal seizure be examined closely they are observed to afford evidence of the existence of processes in operation, animated by purposes precisely similar to those manifested in the dual syndrome of the simple gastrocirculatory attack. There is this difference, however, between the two types of seizure. In the robust forms of the simple gastrocirculatory attack the processes in operation as represented in the gastric section of the dual syndrome are perfectly coordinated and sufficiently effective to accomplish their end, and the attack terminates in expulsion of the contents of the stomach; whereas in the case of the anginal seizure the processes in all their operations are inefficiently organized and abortive, and the purpose of the seizure usually remains unfulfilled. The author's paper is well worth reading in its original form.

British Medical Journal, June 18, 1910.

Suggestion in the Treatment of Disease.—Henry Morris presents an elaborate paper on this subject discussing the topics of mental suggestion, hypnotic suggestion, religious suggestion, the cases treated at Lourdes, compares Lourdes cases cured with cases met with in private practice, gives the history of Lourdes and of former shrines, discusses the relation of miracle cures to the doctrine of the Immaculate Conception, refers to the creative life, mentions Christian Science healing, dwells on the importance of temperament in a propagandist, touches upon the lives of the founders of great religious movements, says that Christian Science lacks even glowworm luminosity and closes with the following quotation from Carlyle: "An inward force has been given to man whereby he is enabled to withstand the pressure of things outward. Obstruction abounded but faith was also not wanting. It is by faith that

man removes mountains; while he has faith his limbs might be wearied with toiling, his back galled with bearing; but the heart within him was peaceable and resolved. In the thickest gloom there burned a light to guide him. If he struggled and suffered he felt that even it should be so; knew for what he was suffering and struggling. Faith gave him an inward willingness, a world of strength wherewith to front a world of difficulty. The true wretchedness lies here: that the difficulty remain and that the strength be lost; that pain cannot relieve itself in free effort, that we have the labor and want the willingness. Faith strengthens us, enlightens us for all endeavors and endurances; with faith we can do all and dare all and life itself has a thousand times been joyfully given away."

Psychopneumatology.—J. Rorie discourses on the interactions of mind, body and soul. The paper is made up mainly of quotations from John Goodsir, who was Professor of Anatomy in the University of Edinburgh. The latter's views, says the author, adapt themselves admirably to the most scientific ideas and to even higher and more incomprehensible problems such as those of life, death, and the hereafter when, the individual having fulfilled his purpose here on this earth, the time has arrived when the psyche and the pneuma have to be withdrawn from their mere material companion, and when the last, in consequence, coming under the dissociative laws of physicochemical action alone returns to the purely inorganic elements of which it has been composed, while the two first, still united and now the depository and register of all the deeds done in the body, continue to pursue their eternal and predestined course.

Berliner klinische Wochenschrift, June 6, 1910.

Radium Therapy.—Eichholz says that there is a decided difference between radium rays and emanations. The local action of the radium rays is inhibition to physiological functions; in strong doses they produce tissue destruction. The rays come into play only in affections which can be reached directly as neoplasms and skin diseases. Great care must be used in applying them. The emanations have an exciting irritative action. They are anti-bacterial and resorbent, and stimulate metabolism. Once taken into the body they activate tissues and organs and are excreted mainly through the breath. Treatment by emanations consists of drinks, baths, inhalations, injections, and applications to the skin. The question whether emanations are absorbed through the skin is not yet definitely settled, nor is that of their excretion by the kidneys. It is proved, however, that during the bath cure, the emanations enter the body, and that a bath cure without a drink cure gives excellent results. The indications for radium treatment are as follows: (a) Chronic inflammation of all kinds, either in the soft parts or in the bones and joints, rheumatism, arthritic processes, neuralgia and chronic purulent exudates; (b) constitutional diseases, scrofula, rachitis, tuberculosis, anemia, chlorosis, arteriosclerosis, diabetes, and obesity; (c) catarrh of the mucous membranes; (d) neoplasms, both in operable malignant and benign tumors; (e) skin diseases with horny proliferation, as chronic eczema and psoriasis; also furunculosis and anomalies of the sweat glands, seborrhea, comedones, acne, etc.; (f) weaknesses of old age and following illness; (g) bacterial diseases (internal disinfection by the drink cure). Contraindications to radium therapy are acute diseases, pregnancy, nephritis, hemorrhages, and gastric ulcer. During treatment frequent examinations of the urine for albumin are indicated.

Münchener medizinische Wochenschrift, June 7, 1910.

The Significance of Ambulatory Typhoid in Children.—G. Brückner says that children between the ages of 11 and 15 years form the class most susceptible to typhoid fever, instead of persons of the second and third decade, as previously supposed. These cases of child typhoid are of importance in epidemiology. The occurrence of epidemics in children from 1 to 15 accounts for many of the instances of regional typhoid immunity. The disease in children runs a very light course, often unrecognizable as typhoid fever clinically, is often untreated, and is therefore of especial danger as a means of spreading the infection. The ambulatory typhoid case in a child is often the source of infection of more or less numerous cases, and so the origin of an epidemic. The fight against these mild cases of typhoid in children is to be carried on by an organized campaign, especially by thorough control of the schools in association with school physicians and teachers. A successful campaign, however, can be carried on only when the practitioner appreciates that children are prone to typhoid infection and that in them it may take a very light form, suggesting only a simple dyspepsia. Wider use of the bacterial institutes on the part of the practitioners is much to be desired, especially in the febrile affections of children without a definite diagnosis. Only by the closest relationship between bacteriologist and clinician will the knowledge of the uncertain types of typhoid fever be advanced, and the campaign against them made effective.

Tuberculosis of the Optic Nerve.—Reye reports the case of a child who died of tuberculous meningitis. At autopsy a tuberculous lesion of the optic nerve was discovered. The author says that such a lesion may be caused by one of three conditions. (1) It may result from a tuberculous caries of the skull bone, which, after destroying the dura, involves the root of the optic nerve; (2) in an existing tuberculous meningitis it may result from a spreading of the tuberculous process along the course of the pial vessels; (3) it may result from metastasis of disease elsewhere, entirely independently of any local lesion. In the case reported there was no involvement of the skull. The case was therefore the result of the second or third of these causes.

Deutsche medizinische Wochenschrift, June 9, 1910.

Alcohol Hand Disinfection without Soap.—Schumburg says that the most diligent scrubbing of the hands with soap and hot water does not render them sterile. Soaking them in absolute alcohol or denatured spirits gives thorough disinfection if the hands are dry. Previous scrubbing not only makes the skin more tender and liable to scale after the alcohol, but the moisture in the skin so weakens the absolute alcohol as to render it much less effective as a germicide. He therefore advises that for operations the hands be soaked in absolute alcohol without previous scrubbing.

Treatment of Pernicious Anemia by Blood Injections.—O. Huber has treated a series of five cases of pernicious anemia by intramuscular injections of small quantities of defibrinated blood with excellent results. The amount injected varied from 20 to 110 c.c. In one case the red blood count rose from 1,200,000 to 4,800,000, and the hemoglobin from 18 per cent. to 92 per cent. in four months. In another case the red blood count changed from 1,460,000 to 5,200,000, and the hemoglobin from 20 to 90 per cent. The third case showed improvement in red cells from 3,200,000 to 5,000,000, and in hemoglobin from 40 per cent. to 70 per cent. The fourth case was still under treatment. The red cells had increased from 650,000 to 2,000,000, and the hemoglobin from 10 per cent. to 55 per cent. The fifth case ended fatally. The author believes that the intramuscular injection of defibrinated blood is a most valuable procedure in severe anemias.

Household and School Prophylaxis of Measles and Scarlatina.—Guiseppe Pecori believes that it is not possible to do much in the way of prevention of the spread of measles by the use of fumigations and disinfection of articles. The virulence of the contagion is short-lived, and the mischief is done in the very early stages of the disease, before the diagnosis is made. The thing that will be of value in this disease is a systematic education of the public to understand the necessity of early diagnosis and immediate and perfect isolation of children sick with measles. At present these children are allowed to go to school and to mix with other children at a time when they should be in isolation. As to scarlatina, the same perfect isolation is needed, and must be maintained for at least forty days from the beginning of the illness. It is questionable whether the actual desquamated scales are contagious, but the skin is capable of being inoculated with germs from the throat, and we know that they retain their vitality for a long time. The contagious thing is the patient, not his surroundings, and the nasopharynx carries virulent germs for a long time after the general symptoms have ceased. The patient, all that he wears or uses, and the persons who take care of him should be carefully disinfected after the disease is at an end. Whenever possible the child should be cared for in a hospital. If he must be cared for at home it is advisable to have everything in his room washed with a disinfectant, and the matresses and other nonwashable articles sterilized by heat. It is important to recognize and isolate the slight and abortive cases also. Many of the cases of albuminuria and nephritis in children are due to an unrecognized scarlatina.—*Gazzetta Medica di Roma.*

Book Reviews.

Diseases of the Genito-Urinary Organs considered from a medical and surgical standpoint, including a description of gonorrhea in the female, and conditions peculiar to the female urinary organs. By Edward L. Keyes, Jr., M.D., Ph.D., Clinical Professor of Genito-urinary Surgery, New York Polyclinic Medical School; Surgeon to St. Vincent's Hospital; Lecturer on Surgery, Cornell University Medical School. New York and London: D. Appleton and Company, 1910.

This work consists of six divisions, containing ninety-one chapters covering 975 pages. The subjects include the diseases of the male and female urinary organs, the male genital organs, syphilis, and a section on genitourinary surgery. It is intended for the use of the student and the general practitioner, but it is of real value to the specialist as well, since it comprises the latest advances in this field of medicine. The chapters on the kidney are particularly excellent because of the admirable presentation of the collected knowledge of our time in a manner quickly and easily comprehensible to the reader. He has given insufficient attention to that keystone of modern urology, uranalysis; its more extensive consideration would be in better keeping with the thoroughness of his work. Many teachers and urologists will differ with him in his technique of instrumental diagnosis of urethral stricture, since he places entire reliance on a therapeutic instrument—the sound. It is also surprising that he has omitted that valuable and time-honored irritating injection test from the proofs of cure in gonorrhea. The section on syphilis, though extremely condensed, covers the subject in a masterly manner. The tonic treatment as originated by Keyes, Sr., occupies a prominent place. The laboratory methods of diagnosing syphilis are reviewed in a dispassionate tone and the diagnostic table of genital sores will be most useful to those not possessing wide experience in these lesions. The section on operative work includes everything from nephrectomy to meatotomy. Occasionally, the author treads on thin ice in the use of his English, but this is pardonable because of the force and virility of his style. He skillfully avoids polemics by blunt statements of personal opinions and experiences on mooted points. The chapters on cystoscopy and gonorrhea in the female by Drs. B. S. and E. D. Barringer are praiseworthy; likewise the two hundred instructive cuts and illustrations.

Lehrbuch der gynäkologischen Cystoskopi und Urethroskopie von Prof. Dr. W. Stoeckel, Direktor der Universitats-Frauenklinik in Marburg a.L. Zweite, vollig neubearbeitete Auflage der "Cystokopie des Gynäkologen. Mit 25 lithographierten Tafeln und 107 Textfiguren. Berlin: Verlag von August Hirschwald, 1910.

Stoeckel has so changed, rewritten, and added to his first work that the present book is practically new. The methodical arrangement begins with descriptions of the various cystoscopes and accessories, and ends with the therapeutics of urethroscopy and cystoscopy. In the first chapter, full honor is accorded to the immortal Nitze for his work, and mild sarcasm to those later "inventors" of wonderful cystoscopes. The painstaking directions in the technique of sterilization of instruments, operator and operative field are commendable, since it is only by strict adherence to these details that the bladder, ureter, and kidney pelvis will tolerate the insult of cystoscopy or ureteral catheterization. In the chapter on complications of cystoscopy, the author recites the difficulties encountered in bringing all parts of the bladder into view, the causes of failure in the operation by malposition of the lamp or prism, and the possible obstructions to the urethral catheter before and after entering the ureter. Later, he describes every known trick employed to engage the catheter tip in the ureteral meatus. All this important information for the cystoscopic student is arranged in logical sequence. The views expressed on the determination of renal function, kidney and bladder pathology, and intravesical foreign bodies are not new. The sections on urinary fistulæ, cystoscopic findings in pre- and post-operative gynecological conditions are instructive. The plates by Frl. L. Krause are well made and are devoted almost exclusively to illustrations of technique. One very interesting plate shows the jaws of a forgotten artery forceps entering the bladder from the abdomen. The colored plates do not compare favorably with those of other similar works. Stoeckel's wide teaching experience befits him for the preparation of this book, which is strongly recommended to beginners in cystoscopy, since those who follow his teachings cannot go astray.

Preventable Diseases. By Woods Hutchinson, A.M., M.D. Author of "Studies in Human and Comparative Pathology," "Instinct and Health," etc., etc. Clinical Professor of Medicine, New York Polyclinic, late Lecturer in Comparative Pathology, London Medical Graduates' College and University of Buffalo. Boston and New York: Houghton, Mifflin Company, 1909.

The author of this work is too well known to require any introduction to either the medical profession or the lay public. The present book is written in the author's usual breezy style. Some of the chapters have already appeared in lay magazines; and the titles are well selected, and will ensure a perusal of the work. "Offering up a guinea-pig for the life of a child" is the alternative title for the chapter on diphtheria; and appendicitis is labeled "Nature's remnant sale." Physicians will enjoy reading the book; and at the same time it is a capital volume for such of the public as desire to know something of things medical. Just now there is a demand on the part of the laity for more information from the medical profession; and the present is one of the two or three volumes best calculated to supply this want. The general tone of the book is healthy, and no one will be the worse for a perusal of the same.

Maladies des Veines et des Lymphatiques. Par MM. Paul Launay, Chirurgien des Hôpitaux de Paris, et Henry Brodier, ancien chef de clinique chirurgicale de la faculté de médecine. Avec 36 figures intercalées dans la texte. Paris: Librairie J. B. Baillière et fils, 1910.

This pamphlet is the twelfth in the "Nouveau Traité de Chirurgie" series. The authors approach their subject not only from the standpoint of the clinician and operator but also from that of the pathologist. The novel accidents and diseases of the venous and lymphatic systems are ably discussed with an exceptional thoroughness. Interesting illustrations accompany the text and serve to make a very acceptable addition. Diagnostic points are carefully brought out, and the most recent theories in etiology serve to maintain an interest on the part of the reader.

The Stomach, Intestines, and Pancreas. By W. C. Bosanquet, M.A., M.D., Oxon., F.R.C.P., Assistant Physician to Charing Cross Hospital and to Brompton Hospital; and H. S. Clogg, M.S., Lond., F.R.C.P., Eng., Assistant Surgeon Charing Cross Hospital, Senior Surgeon to the Evelina Hospital for Children. Edited by James Cantlie, M.A., M.B., C.M., Aberd., F.R.C.S., Eng., Surgeon Seamen's Hospital Society, Lecturer on Surgery, London School of Tropical Medicine. New York: William Wood & Company, 1910.

This book is the second volume of the Medico-Chirurgical Series edited by Dr. Cantlie and designed to represent in one and the same publication the views of both physicians and surgeons upon special subjects in medicine. The book is divided into five sections, the first of which contains a brief description of the surgical anatomy of the stomach, intestines, and pancreas, the matter being presented in a form available for the physician or surgeon in diagnosing affections of these organs in the sick room and in dealing with them on the operating table. Various peritoneal pouches and the related lymphatic channels are especially described especially fully.

Section II deals with the functional and organic affections of the stomach, the various forms of gastritis, gastric and duodenal ulceration, obstructions of the pylorus, benign and malignant tumors of the stomach being considered in order. The various chemical tests in the diagnosis of these affections are given ample space and whenever surgical treatment may be indicated the technique of the operation and the after-treatment of the patient are fully considered. A similar plan is followed in the two following sections dealing with the affections of the intestines and the pancreas. Appendicitis is treated with a wealth of detail. It may be noted that the authors believe in expectant or "medical" treatment of this affection much more than it is the fashion on this side of the Atlantic. The book is closed by a short appendix giving a few specimen prescriptions used in the treatment of gastrointestinal affections.

The book does not claim to be an exhaustive treatise of the subject considered. The diseases in question are discussed for the most part dogmatically, but this makes the volume so much the more valuable for the practical use for which it is intended. Its chief merit, however, lies in the very plan under which it has been conceived, namely, the viewing of the subject matter from the standpoint of both the physician and the surgeon. It is heartily recommended to men active in either of these fields of medical work.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-fifth Annual Meeting, Held in Washington, D. C., May 3, 4, and 5, 1910.

THE PRESIDENT, DR. EDWARD P. DAVIS, PHILADELPHIA, IN THE CHAIR.

AN address of welcome was delivered by Dr. I. S. Stone, Washington, D. C., which was responded to by Dr. Seth C. Gordon, Portland, Me.

Primary Carcinoma of the Female Urethra; Hematoma of the Broad Ligament Recurring with Pregnancy; Fibroid Tumor of the Ovarian Ligament.—Dr. MANTON of Detroit reported three unusual cases in great detail, and said that primary carcinoma of the female urethra was among the rarest of malignant manifestations. A careful search of the literature up to 1910 gave the reports of but 35 cases, including his own, of primary cancer of the female urethra. A careful search of the literature failed to reveal the report of a similar case of hematoma of the broad ligament recurring with pregnancy. Regarding the case of fibroid of the ovarian ligament, the only reference to the occurrence of fibroids of the ovarian ligament which he had not been able to find, were the two cases reported by Doran in 1896. In both of these cystic cavities existed.

DR. REUBEN PETERSON of Ann Arbor, Mich., had operated on a woman four or five years ago for carcinoma of the meatus which extended up into the urethra about one-half inch. Incontinence followed, with subsequent prolapse of the bladder mucosa through the remainder of the urethra. The woman complained of this, and so he sewed up the opening and made an opening from the bladder into the vagina. Then she complained of incontinence. He did a colpocleisis, and made an opening into the rectum. This woman had passed her urine through the rectum ever since, and to-day she was as well as one could be in that condition. The second case of primary carcinoma of the urethra happened a short time ago. It looked like a urethral caruncle. However, microscopical examination showed it to be primary carcinoma. In this case he removed about one-third of the urethra, and there had been no recurrence for two years.

DR. CLEMENT CLEVELAND of New York had had two cases of primary cancer of the meatus, on one of which he did a radical operation, but the disease returned. In the second case he resorted to the use of the actual cautery, with gratifying results. He called attention to the value of radium in these cases.

DR. J. RIDDLE GOFFE of New York had had one remarkable case of malignant urethral caruncle or primary carcinoma of the urethra. This was a number of years ago. The woman gave a history of having been operated on by Dr. William T. Lusk, six years previously. For six years the woman was comparatively comfortable. She had control of the urine, but passed it through a buttonhole which was made in the urethra by Dr. Lusk. At the time she consulted the speaker there was a cauliflower excrescence protruding from the meatus, which was of a bright cherry-red color, exquisitely sensitive, and the source of constant pain. With the cautery he removed all of the urethra and the surrounding tissue from the posterior angle of the urethra, taking away all but one-fourth of the urethra at the neck of the bladder. The woman made a comfortable recovery, but inside of a year the disease returned, and she died with great suffering about a year after the procedure he had instituted.

DR. FREDERICK J. TAUSSIG of St. Louis, Mo., reported a case of carcinoma of the urethra that had occurred in the practice of Dr. Drosett and himself. The patient was kept under observation for a long time. He saw her in 1900, and at that time there was a urethral caruncle, chronic urethritis, a retroverted uterus, and a relaxed pelvic floor. He operated on her for the retroversion and pelvic floor, but did nothing further to the urethra. Three years later the patient returned with a history of bloody discharge which had existed for three weeks. When he examined her he found an infiltrating cancer involving the lower part of the urethra. Operation consisted in removing the entire urethra to the point of its entrance in the bladder, putting a pursestring suture around the opening which was left in the bladder so as to strengthen the muscular tissue there, and then, as a further precaution, removing the external inguinal glands on both sides, although there was no glandular enlargement at the time. The patient recovered from the operation, although there was partial incontinence. A year and a half after the primary operation, the patient returned with recurrence in both inguinal regions and higher up. She was kept at the skin cancer hospital two or three months under trypsin treatment, but with no benefit. The patient died, and at autopsy there was absolutely no recurrence at the primary site. The tissues about the urethra and bladder were absolutely free from carcinoma, and the glandular involvement was not merely confined to the lymphatics, but it involved the liver and spleen.

DR. SETH C. GORDON of Portland, Maine, reported the case of a woman, seventy years of age, who had a growth of the urethra for nearly a year, and at the time she came under his care she had been treated by caustics for six or eight months. The growth was as large as a walnut and bled on the slightest touch. He removed the growth with three-quarters of an inch of the urethra, bringing the remainder of the urethra down and attaching it. The operation was done four years ago, and she had had no return of the disease. Microscopic examination showed it to be carcinoma.

DR. HIRAM N. VINEBERG of New York had a case of primary carcinoma of the urethra some years ago which involved the anterior third of the urethra. He did a thorough operation, went close to the vesical sphincter, and as a result there was slight incontinence. Prior to the operation the woman had no pain or bleeding. Microscopic examination showed the growth to be carcinoma. He did a plastic some time afterward and found in trying to build up the artificial urethra and in bringing the stump of the urethra forward it was only partially successful. The woman could retain her urine for an hour or so while in bed. She was under observation three years, and during that time there was no recurrence.

DR. HENRY T. BYFORD of Chicago had had one such case, and called attention to the fact that this disease of the urethra was not so rare as one would judge from the cases reported.

DR. FRANCIS H. DAVENPORT of Boston had seen a woman in whom nearly one-quarter of the urethra was involved with carcinoma. Radium was tried for several months, but only externally from the vaginal side. Finally the growth became so large that there was retention of urine, and a suprapubic fistula had to be made which relieved the woman of her symptoms, but within three months after that she died from exhaustion.

DR. I. S. STONE of Washington, D. C., said it was essential to know about how wide the excision should extend, and how far the malignant process extended when one began to operate on these cases of carcinoma of the urethra.

DR. JOSEPH BRETTAUER of New York had repeatedly had cases sent to him which were diagnosed as carcinoma of the urethra, but which turned out to be urethral carbuncle by microscopical examination. It was difficult to decide at times whether the growth was malignant or not.

Dr. Edward L. Duer of Philadelphia said that not long ago he did an extensive operation for a carcinoma of the urethra which extended well into the end of the vagina. The disease returned in a short time after the operation, when radium was used with a gratifying result.

Dr. Manton, in closing, questioned whether all the cases reported were really primary carcinoma of the urethra. Many cases of periurethral carcinoma were mistaken for urethral malignancy, and no doubt some of them belonged to this class.

Bilateral Tubal Pregnancy; Coincident Development.—Dr. Palmer Findley of Omaha reviewed the literature on the simultaneous development of a fetus in either tube. He found twenty-eight cases reported as examples of bilateral tubal pregnancy, but only eight were unquestioned as being of simultaneous development. Of the twenty cases of doubtful identity, the clinical diagnosis was not supported by the macroscopic and microscopic findings of fetal structure in the two tubes. To these eight cases the author added a ninth in which there was a probable simultaneous development of both fetuses in either tube, with rupture of the right tube, and the escape of the ovum through the fimbriated end of the left tube. The escape of the two ova was probably simultaneous. The pelvis was full of blood and there was a general peritonitis. Decidual tissue and chorionic villi were found in both tubes, but neither fetus was discernible. Both ovaries were cystic and adherent. In the right ovary was a fresh corpus luteum. An abdominal section was performed with the removal of both tubes and escaped blood. The abdomen was drained. Death followed from general peritonitis.

Dr. Douglas Bissel of New York reported a case of successful reimplantation of a pelvic kidney in the female, and made some remarks on the surgical treatment of kidney misplacements in the true pelvis.

The Chief Cause and Prevention of Postoperative Cystitis.—Dr. Joseph Taber Johnson of Washington, D. C., emphasized the necessity for a more strict prophylaxis, and said that when cystitis was diagnosed, a more active and continuous treatment should be instituted, not only to bring about an early cure, but to prevent its transition from an acute to a chronic condition. Cystitis occured in women more frequently after abdominal than other operations, where there were confined the evil influences of both traumatism and bacterial infection. Where patients were catheterized several times daily for a week or even longer, the conditions were present which easily resulted in the production of a cystitis unless great care was practised to prevent trauma or infection.

Improved Operation for Extreme Cases of Procidentia and Cystocele.—Dr. J. Riddle Goffe of New York said that procidentia and cystocele were the results of three lesions: first, a descent or relaxation of the supports above. Second, laceration of the perineum to the second degree, and, third, stretching and tearing of the fascia at the base of the bladder, producing a hernia. The support below was only indirect and of secondary importance. The true principles of support was that of suspension, and in order to secure a permanent result after operation the organs must be suspended or hung from above. The broad ligaments, including the round ligaments, and the fascia lata were the proper tissues to utilize for this support. As a rule, these conditions obtained in patients at or beyond the menopause. In childbearing women, especially if they desired children, the uterus should be carried into normal position and retained there by shortening the uterosacral and round ligaments. The bladder was then freed from all its attachments to the vagina and lateral structures and carried up and spread out over the face of the uterus and broad ligaments. The vaginal sheath and wall were then cut away in the median line sufficiently to bring it up snug against the base of the bladder when stitched from side to side. If the perineum was torn to the second degree and a rectocele was present, the floor of the pelvis was restored. In patients at or beyond the menopause the uterus was removed, the broad ligaments beginning with the round ligaments at their upper borders were then stitched together across the pelvis from side to side, from the round ligaments down to the cardinal ligaments, thus turning the raw edges of the broad ligaments posteriorly. Upon this plane of tissues thus constructed, the bladder was then spread out and stitched in such a way as to carry the bladder high in the pelvis, thus restoring the base of the bladder as it was originally to a comparatively immobile foundation, and restoring the hinges and the coruna of the bladder as so graphically described by Dr. Kelly. The upper end of the vagina was also stitched to the broad ligament, bringing it up taut against the base of the bladder, the fascia lata was cut away and stitched as previously described, and the perineum repaired. To accomplish this work it was necessary at the beginning of the operation to make a longitudinal incision in the vagina along its anterior wall throughout its entire length and dissect the bladder freely from all its attachments. The results of this work were most satisfactory in every particular, and were likewise permanent.

Dr. Charles Jewett of Brooklyn said he had had the privilege and pleasure of watching Dr. Goffe do this work, and his technique was the most complete and perfect of any he knew. He had been especially gratified to observe that he concluded the operation by securely building up the perineal buttress beneath the bladder.

Dr. I. S. Stone of Washington, D. C. said this method or a slight modification of it had given him the utmost satisfaction. He had no knowledge of any case of cystocele or prolapse having recurred if this work had been properly done. He did not mean to say that his work was better than others, but the possibilities of this operation were so thoroughly good that if any surgeon would try it, he would be rewarded by perfect success.

Dr. Henry T. Byford of Chicago described a modified operation which he did in these cases.

Dr. Seth C. Gordon of Portland Maine, said he was satisfied all of the work his profession had been doing heretofore in their efforts to fix the uterus, after they had had complete procidentia, had been of very little avail. The uterus gave way after a while. Of late he had been removing the uterus in every case and stitching up remnants of the vagina to the broad ligaments, and fixing it as well as possible, and he believed they opened a new line of work in that direction when they began by removing the uterus.

Dr. Clement Cleveland of New York said he had followed the operation described by Dr. Goffe for some years. In his hands it had succeeded in the great majority of cases. He had done it over thirty times, and he could recall no case in which it had not been a success.

Dr. C. C. Frederick of Buffalo said he had been doing this operation for the last four or five years, and he had taken the position that in cases of advanced procidentia the removal of the uterus, as a part of the operation, was the *sine qua non* to success. He had done from seventy-five to eighty of these operations for procidentia, and had invariably used catgut for suture material and had not had any ill results from it.

Dr. J. M. Baldy of Philadelphia said this operation was so extensive in its denudative qualities and so dangerous in its possible results as to be absolutely unwarranted as a simple cystocele operation.

Dr. Leroy Broun of New York said he had seen Dr. Goffe do this operation often. He had done it himself, and he had had the privilege of seeing one of his cases

upon whom he had operated, and a more ideally perfect result he had never seen. The uterus was in excellent position.

Dr. George Gray Ward, Jr., of New York said that Dr. Goffe taught him this operation five or six years ago, since which time he had done it in several instances, and he could only bear out what Dr. Broun had said, that the results spoke for themselves. He had not seen a failure from the operation where it had been properly done. The patient was satisfied, and that was the best part of the game after all.

Intramural Sequestration and Fixation of the Corpus and Fundus Uteri for the Cure of Procidentia Uteri Existing in Women with Whom Further Pregnancy Is Not Possible.—Dr. Philander A. Harris of Paterson, N. J., said he had subjected six women to a possibly novel procedure for the cure of procidentia uteri, and since these operations had been followed by most gratifying results, he wished to describe the operation for whatever value it might possess for others. The following was the author's description of the operation: "Cut a median line abdominal incision from one inch beneath the umbilicus for three or four inches, and deliver there through the corpus and fundus uteri. While an assistant grasps and draws the uterus well out of the incision, the cut edges of the parietal peritoneum are sewn to and around the uterus at the junction of the cervix with its corpus. This sewing crosses the broad ligament at either side about two inches away from the fundus uteri. After thus attaching the opposing cut edges of the peritoneum to the uterus and the broad ligaments, the suturing is carried upward to the top of the incision, thus closing the peritoneal cavity with the corpus and fundus still held in the grasp of the assistant, and, of course, outside of the peritoneal cavity. While the assistant continues to hold the uterus outside of the incision, an iodoformed 5-16th inch gauze and rubber tissue drain is placed on top of the muscle and beneath the fascia to a point two or three inches to one side of the incision, at which point it is made to emerge from a small stab wound. The tapering tail of this drain is placed in the wound between the peritoneum and fascia. The anterior surface of the corpus and fundus uteri are next denuded with a knife, after which the fundus is seized with a hook and volsella, with which it is dragged upward as far as possible toward the umbilicus, and made to nestle in the incision anterior to the peritoneum and between the recti muscles. The fascia is next sewed from the umbilicus downward with running stitches of chromicized catgut. Wherever the corpus and fundus uteri are in contact with the fascia as it is being closed, the stitches are made to include sufficient musculature of the uterus to fix it in its sequestered position. The sewing of the skin with a running catgut suture completes the operation unless the patient is obese, in which case a small drain is placed between the fascia and the skin and made to emerge from a stab wound two inches or more to one side of the incision. The application of the usual gauze dressing and adhesive straps completes the operation. The drainage tubes are partly withdrawn in two or three days, but generally not removed until ten days or more after operation." "No one," he said, "should perform the operation of intramural sequestration upon any woman with whom pregnancy was still possible, but since they were often asked to relieve patients from the symptoms produced by procidentia uteri after the menopause, it would be realized that there were very many cases for whom this operation might be recommended if, on further trial, it was found to possess a special value to which he was inclined to attach to it.

Gallstones During Pregnancy and the Puerperium.—Dr. Reuben Peterson of Ann Arbor, Michigan, read a paper on this subject in which he drew the following conclusions: 1. Gallstones were most commonly met with in women between the ages of twenty and thirty-five. 2. Gallstones were more common in women than in men. 3. There were reasons for thinking that child-bearing had something to do with the frequency of gallstones in women. 4. This was borne out by finding that in 542 patients where the gall-bladder was palpated during the course of abdominal operations, gallstones were found to be present in 64 or 11.8 per cent. 5. The percentage of patients with gallstones, who had borne one or more children, was 75 per cent., as against 63.7 per cent. in women who had no gallstones. 6. In the present series of pregnant patients with cholelithiasis, in nearly one-third of the cases the onset of the attack was at the fifth month of gestation, or at the time when the uterus was approaching the level of the umbilicus and beginning to crowd the intestines toward or upon the bile passages. 7. In the puerperal cases the onset of the attack in one-half of the cases was during the first seven days post-partum. 8. Chills, elevation of temperature, associated with jaundice, were frequent in gallstones complicating pregnancy and the puerperium. 9. In the series studied there was a surprisingly large percentage of pregnant patients with jaundice, 15 out of 25 or sixty per cent. 10. Only one out of the ten puerperal patients had jaundice. 11. The operative mortality for the twenty-three pregnant patients was 13.04 per cent. 12. The operative mortality for the puerperal cases with cholelithiasis was 11.1 per cent. 13. In the pregnant patients with cholelithiasis more than one-half of the stones were in the gall-bladder alone. The same may be said of the puerperal cases. 14. It was probable that there was no greater tendency for gallstone operations to interrupt pregnancy than was the case with other abdominal operations during various periods of gestation. 15. It was advisable, when cholelithiasis complicated pregnancy and the puerperium, to choose the operative procedure which could be performed in the shortest possible time consistent with the existing conditions. 16. The condition of the pregnant patient as regards the cholelithiasis should be the determining factor as to when the operation should be performed, whenever possible the operation should be postponed until the child was viable. 17. The diagnosis of cholelithiasis during pregnancy and the puerperium would not be difficult in typical cases, if the possibility of the complication be borne in mind. Much reliance could be placed upon the jaundice which seemed to be more prevalent in pregnant than in non-pregnant women with gallstones.

Dr. W. Francis Wakefield of San Francisco believed a very large percentage of women had gallstones, and in carefully studying the histories of cases a large percentage of the women could trace the beginning of the symtoms to pregnancy. The gall-bladder should be examined every time the abdomen was opened, and every time gallstones were found in the gall-bladder they should be removed at that time. It was a great mistake, however, to operate on gallstones during pregnancy if it could be avoided.

Dr. Philander A. Harris of Paterson, N. J., said that if a patient had gallstones, he did not think the decision to operate should rest upon the mere fact as to whether the patient was pregnant or not. The decision to operate should be governed by other conditions, no matter whether gallstones occurred in connection with pregnancy or not.

Dr. A. Lapthorn Smith of Montreal questioned whether it would be a good thing to operate on a woman for gallstones who was six months advanced in pregnancy. The pregnant woman should be carried along with morphine and other treatment until she had been delivered of her child, and then operated on for the removal of the gallstones.

Dr. W. Gill Wylie of New York had been watching

the gall-bladder whenever he opened the abdomen through an incision large enough to introduce his hand, and he had found that the percentage of gallstones was very much greater than he had expected.

Dr. Hiram N. Vineberg of New York stated that a few years ago he was called in consultation to see a case of supposed puerperal sepsis. The woman had been delivered ten days before. She was very ill; had a temperature of 104.5°, pulse 120, and complained of pain on the right side of the lower part of the abdomen. She had given no history of gallstone attacks prior to that. He examined her carefully and found a distended gall-bladder and made a diagnosis of cholecystitis. At the operation the gall-bladder was found full of small stones, with mucopurulent fluid in the gall-bladder. The woman made a good recovery.

Dr. Henry T. Byford of Chicago said that undoubtedly a great many women had gallstones, and perhaps in most of the cases, instead of gallstones originating from pregnancy, they were old instances of people who had been known to have had indigestion, and whose cases had not been diagnosed. Many of these women had had gallstones for a long time, and pregnancy was merely the cause of the first recognizable symptoms of gallstone trouble.

Dr. John F. Thompson of Portland, Maine, reported the case of a woman, three or four months pregnant, upon whom he operated and found a perforation of the gall-bladder with stones and pus and some bile, which fortunately were shut off by folds of omentum. The operation was not complicated. The patient had no interference with pregnancy, and was now three months more advanced.

Dr. Henry Hough of New Bedford, Mass., had operated on two cases of gallstones during pregnancy. One was a woman, twenty-three years of age, and two months pregnant. She had stones in the gall-bladder and in the duct. She also had chronic pancreatitis. Drainage and removal of the stones resulted in a cure, and about one month after operation she was delivered of a three months fetus. The other woman was five months pregnant, who had acute cholecystitis with gallstones in the gall-bladder. The gallstones were removed from the gall-bladder, and drainage established, followed by a prompt recovery. The woman went on to full term.

Dr. Richard C. Norris of Philadelphia said that operations on gallstones during pregnancy should be determined by the character of the cases. If the case was an aggravated one, the woman should be relieved of her gallstones independent of the pregnancy, but if it was a case where one could tide the patient over until labor had been completed, it was better to do so.

Anastomotic Repair of the Ureter.—Dr. Malcolm McLean of New York said that cases might occur where end-to-end anastomosis was desirable and preferable to implantation into a slit wound. He described a method which offered a means of securing anastomosis and at the same time providing for the safe conduct of the urine past the point of repair during the first critical hours after the operation.

President's Address: American Gynecology.—The President, Dr. Edward P. Davis of Philadelphia said that American gynecology had its origin in the crude obstetric practice of fifty years ago. The necessity for repairing the injuries of labor developed the genius of Sims and Emmet, and American ingenuity added a new branch to surgical science. As obstetric surgery had developed and asepsis was introduced, gynecology had become more and more abdominal surgery. This had been the case, not only because better obstetrics had lessened the injuries of labor, but because women had those abdominal lesions most easily recognized and most frequently occurring. At present the modern gynecologist operated upon men and women alike, the surgeon in turn performing many operations on women. Today the tendency of development in gynecology lay in the study of the normal relations of the abdominal and pelvic viscera, the determination of the dynamics of the abdomen and pelvis, and the recognition of those causes which produced abdominal and pelvic ptosis. The repair of lacerations of the genital tract did not suffice to cure these cases. The pelvic viscera must be brought into such relation with the abdomen and its contents that the dynamics of the abdomen shall maintain health for the individual, and not disease. That this subject was today of primary importance was shown in the fact that this society and the American Surgical Association were about to engage in a joint discussion of this problem. Modern surgery having conquered the world of technique, it sought other fields of conquest. The operation for cancer seemed to have reached its anatomical limitations, but the cause of cancer remained unknown. Gynecology today was especially charged with the task of studying the cause and the mode of growth of malignant disease, so that operation might be wisely chosen and performed. In no branch of medicine had so great advance been made in recent years as in obstetrics. Pathological chemistry had thrown new light upon toxemia and eclampsia and lessened the frequency and mortality of these grave complications of parturition. Obstetrics offered abundant work for the future. Toxemia and eclampsia were but partly understood. It was still not proven that vaginal delivery, after opening the pelvic girdle, was not accompanied by such injuries that abdominal delivery was not better, and even in the repair of lacerations the final word had not yet been spoken. It was still an open question whether in puerperal sepsis we could do more than feed and stimulate the patient. Gynecology was an American science, of which America might well be proud. Let us see to it that it served faithfully the land of its birth.

The Use of the Uterine Stem.—Dr. Francis H. Davenport of Boston said that twenty years' employment of the stem had convinced him of its efficacy and safety. The principal use was in dysmenorrhea of a particular type, which was characterized by severe pain coming on with, or soon after, the appearance of the flow, and rarely lasting more than twenty-four hours. The pathological condition in these cases was generally as follows: A rather small, usually anteflexed uterus, a relative stenosis of the internal os, a tendency to the formation of connective tissue at this point, and exquisite sensitiveness to the passage of the probe. The attempt of the uterus to get rid of the menstrual blood past an extremely sensitive, somewhat narrow os, gave rise to pain until the general relaxation of the tissues which accompanied menstruation had taken place which was usually within twenty-four hours. A solid, hard rubber stem was sewn into the uterus and allowed to remain from four to six weeks, usually with complete relief of the dysmenorrhea. The stem was also useful in some cases of sterility and amenorrhea from lack of development.

Fibroid Tumor Complicatng Pregnancy and Rendering Natural Labor Impossible.—Dr. B. F. Baer of Philadelphia said that early in his medical career it was his fortune to see two cases of pregnancy complicated with fibroid tumor, in one of which rupture of the uterus occurred during labor, followed by death of both the mother and child. In the other case death resulted from septic peritonitis in consequence of injury to the soft parts following instrumentation for dystocia caused by complicating fibroid. The child had perished during the labor. The first case was attended by a midwife. To the other he was related as an assistant. This dreadful experience impressed upon him the fact that pregnancy complicated

with fibroid tumor was a most serious condition, and investigation of the literature soon convinced him that he had only witnessed a disaster that was not uncommon in the period that had passed. After reviewing the literature, Dr. Baer reported six cases. The first was one of multiple fibroid tumor of the uterus complicating pregnancy, with hemorrhage and miscarriage; myomectomy and oophorectomy; recovery. The second was one in which he resorted to supravaginal hysterectomy for a fibroid tumor complicating pregnancy and rendering labor impossible; recovery. The third was one of fibroid tumor complicating pregnancy, hemorrhage, and miscarriage, in which supravaginal hysterectomy was done; recovery. The fourth one was a fibroid tumor in the posterior wall of the uterus complicating pregnancy. Pelvic incarceration rendered the continuance of pregnancy dangerous and labor impossible, and supravaginal hysterectomy was done at the fifth month, followed by recovery. The fifth was one in which pregnancy was complicated with fibroid and ovarian tumor. Supravaginal hysterectomy was done, followed by recovery. The sixth case was a pregnancy complicated with fibroid tumor in the lower zone and broad ligament, blocking the pelvis and rendering natural labor impossible. Abdominal hysterectomy was done at the seventh month, with recovery. The cases cited showed the great importance of operating on cases in which the tumors caused such obstruction as to interfere with the natural delivery of the child.

Dr. W. Gill Wylie of New York said that if the fibroid tumor was so large as to interfere with the delivery of the child, it should be removed; but if nothing disturbed the women's health, so far as the fibroid was concerned in the way of hemorrhage, and the tumor or tumors were situated above the os internum, undoubtedly the woman could be delivered of a healthy child in the natural way.

Dr. Hiram N. Vineberg of New York said that he had seen five or six cases in which pregnancy was complicated by fibroid tumors. It was rare that we were called upon to operate on these women during pregnancy, for the majority of them would deliver themselves normally.

Dr. Malcolm McLean of New York said that not infrequently fibroid tumors took on a retrograde movement in pregnancy as the result of that condition. He had seen two such cases in which the tumors almost entirely disappeared after delivery.

Dr. Seth C. Gordon of Portland, Me., said that where a woman had a fibroid tumor that was troubling her, she had better have hysterectomy performed.

Dr. Reuben Peterson of Ann Arbor, Mich., had seen three cases of fibroid tumors complicating pregnancy in the last year. While we should always deal with these cases conservatively and give every chance to the women, we should still remember that the fetus should have a chance, and if the pregnant woman could go on without jeopardizing her life without an operation she should have that privilege.

Dr. Edwin B. Cragin of New York said that within the last three months he had done a cesarean section in a case of fibroid tumor obstructing the canal complicating pregnancy. On the other hand, they had had a large number of cases at the Sloane Maternity which had given no trouble.

Dr. I. S. Stone of Washington, D. C., did not believe in the disappearance of fibroids unless degeneration took place, or unless necrosis occurred and a submucous abscess formed and discharged. A fibroid might disappear in that way or by twisting of the pedicle, getting separated from the uterus and disappearing.

Dr. Charles M. Green of Boston said that in one case he found the pelvis of a woman filled with a large fibroid tumor. During transmission to the hospital the fibroid ascended out of the pelvis, and when he saw the woman and could reach the os he found a breech presentation. They gave her further time, the fibroid ascended out of the way, and the woman was delivered of a living child, and made a normal convalescence.

Dr. Edward Reynolds of Boston said that two or three years ago he saw a young woman who was pregnant with a fibroid in her uterus. She miscarried. He determined the position of the fibroid with fingers inside the uterus and the hand outside. He operated on her for other causes about a year ago, and found at the site of the fibroid no tumor whatsoever, but a white, comparatively bloodless area in the uterine wall, which evidently represented complete disappearance of the fibroid.

Dr. Willis E. Ford of Utica, N. Y., alluded to the influence which pregnancy had upon a fibroid tumor, and recalled the case of a girl whom he saw before her marriage with an intramural fibroid which reached half way up to the umbilicus. He was called to see her after her marriage, at which time she was pregnant at the fifth month. This was fourteen years ago. He had made arrangements to do a Porro operation. Fortunately nothing happened. She was delivered in the normal way, and had a boy now thirteen years of age. The other day he examined her and found that the fibroid tumor had entirely disappeared.

Dr. Richard C. Norris of Philadelphia had seen tumors situated in the lower segment of the uterus retract themselves, being drawn out of the way by the action of the longitudinal fibers, and disappear when he was about ready to do a cesarean section, and the woman he delivered spontaneously.

Dr. George Tucker Harrison of New York said that in negro woman myomata were much more common than in women of the white race. The position of a myoma was not a bar to conception, and the proof of this was found amongst the negro race.

Surgery of the Upper Pelvic Floor by Direct Suprapubic Approach.—Dr. William M. Polk of New York spoke of the need for further development of the surgery of the upper pelvic floor by direct suprapubic approach, and illustrated the subject by referring to eleven cases upon which he had operated. One was a case of complete prolapse of the uterus. Two were cases of partial prolapse, the cervix resting at the ostium vaginæ. Five were cases of retroversion with adhesions. Three were cases of retroversion without adhesions, and one a case of prolapse of the pelvic floor subsequent to hysterectomy performed some years previously. He described in detail his method of operating.

(To be continued.)

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held May 16, 1910.

The President, Dr. Reynold Webb Wilcox, in the Chair.

The Paradox of the Tubercle Bacillus.—Dr. Ira Van Gieson read a paper with this title (see page 52).

Dr. James Ewing said that if we had to deal with a nonacid-fast form of the tubercle bacillus, then we were face to face with a question which was second in importance only to the discovery of tubercle bacillus itself. If such be the case, then a large part of the history of tuberculosis would have to be revised. Much's work was of very great importance, and although his articles had been common property for the past year and a half, not a single important contribution bearing on the subject had appeared in this country, barring perhaps one. Dr. Van Gieson, therefore, had brought up for discussion an extremely important subject, and was the first one in this country to submit to critical consideration the data upon

which Much had based his important conclusion. It was a rather curious fact that although the tubercle bacillus had been discovered as far back as 1881, such simple problems as its morphology and staining properties were still unsettled. In its development the tubercle bacillus did not always assume a rod-shaped form; it might appear as a row of acid fast granules. Whether these granules could lose their acid-fast quality while still retaining their viability and infectiousness was a very important question very difficult to prove. Dr. Ewing himself had not been able to find proof of such a possibility. He had found that granular bacilli after Gram's stain were sometimes more abundant in old lesions than after the ordinary carbol-fuchsin stain. He was quite unconvinced that Gram positive, non-acid-fast, still viable tubercle bacilli or cocci, did not occur so frequently nor in any such numbers as Much had claimed.

Dr. H. G. Piffard said that Dr. Van Gieson had spoken of the non-visible forms of tubercle bacilli and he would like to say a word regarding the non-existent forms. There were many, Dr. Piffard said, who did not look upon the tubercle bacillus as a specific organism, and he had expressed his own views on the subject in an article entitled "Some Problems Connected with Tuberculosis," which was published in the *New York Medical Journal* about a year ago, in which he had referred to the fat and other acid-fast bacilli, and their close similarity to the tubercle bacillus, and had emphasized the importance of a more improved technique in the bacteriological diagnosis of tuberculosis.

Intestinal Infections in Children.—Dr. Joseph E. Winters made some remarks on this subject. He stated that the excessive mortality which statistics showed to exist among infants was largely limited to those which were bottle-fed. Ninety-eight per cent of the mortality was among infants in the tenement house population, and it was unquestionably due almost exclusively to the kind of feeding which these infants received. This gave rise to infectious processes which might prove rapidly fatal from the conditions set up in the intestines, and which, if more prolonged, involved other portions of the system. After the first week, bronchopneumonia was extremely common, and various complications might arise, such as pleuritic effusion, otitis media, etc. The treatment of these patients should be based strictly on physiological principles. Ordinary cow's milk, animal broths and cereals were not only useless, but positively injurious in the case of young infants. The first thing to do was to clean out the intestinal canal thoroughly with a large dose of ice-cold castor oil, which was the one remedy adapted for this purpose. If it was vomited, the dose was to be repeated. Where vomiting was a feature, there was nothing so efficacious in checking this as hot water in drops, administered with a medicine dropper. For a suitable interval after the dose of oil, nothing whatever was to be given, not even water. Then water alone should be given for a considerable time, in small quantities, and not too frequently. Finally, the infant was placed upon a food composed of the top half ounce of quart bottles of milk (at first, two bottles, and afterwards, three or more bottles), properly diluted and having lime water added to it. This afforded a flocculent protein which closely approximated mother's milk. The results of this treatment had proven eminently satisfactory and the lives of many infants had been saved by it. As for the milk used for this purpose, it was desirable that it should be cooled immediately after being drawn, placed in bottles, and afterwards kept at a temperature of 40° F. Pasteurization or any kind of sterilization was of no service whatever, as was clearly shown by mortality statistics. Later, the top ounce, instead of half ounce, from quart bottles of milk should be employed, and in older infants the portion of the milk sterilized would vary according to the age of the child. In those still older farinaceous food, properly prepared, was as much of a specific for the diarrhea as quinine was for malarial fever, or mercury for syphilis, and the results from its administration alone were often marvelous.

Dr. Henry S. Stearns said that while the method of treatment of the intestinal infections in children recommended by Dr. Winters was very satisfactory for those who were in a position to use it, most of these patients, perhaps 98 per cent., came from the tenements, and were unable to get either the quantity or the quality of the milk that was essential to carrying out his method of feeding. In those cases we must make some compromise. It would be futile to tell the parents of these poor children to take "the top of the bottle" of four to six bottles of good milk, so we had to do the best we could for them.

Dr. Henry D. Chapin said that in spite of the emphatic manner in which Dr. Winters had enunciated his views on feeding in the treatment of the intestinal infections in children, he could not agree with him excepting on one or two points. One of these was the necessity for the rapid cooling of the milk, and in connection with his work with the Milk Commission of the County Medical Society he had frequently seen an illustration of the fact that milk from a dirty dairy gave a low bacteria count by rapid cooling. The fact should not be lost sight of, however, that milk could not be kept at a temperature of 40° F. in the average refrigerator. In some of these cases of intestinal infection in children whose digestion was impaired it was better to give the feedings less often than was recommended by Dr. Winters—even every four hours. As to the amount of fat in the feeding, Dr. Chapin thought the pendulum had swung too far, and that we would see cases of rickets and malnutrition from nonfat feeding. The percentage of fat in the top few ounces of the bottle varied considerably, and if we could only convince Dr. Winters to go a little deeper into the bottle he would probably see his babies thrive quite as well, if not better. As a matter of fact, every time one was putting cow's milk into a baby's stomach one was putting in a foreign body. If we could keep the children at the breast, we would see very few cases of intestinal infection. Dr. Chapin said he was the first to call attention to the fact that the proteins of milk had two functions, a developmental function as well as a nutritional function. The casein of cow's milk coagulated in tough, stringy masses, and every time we put cow's milk into a baby's stomach we were putting in a food which was intended for an animal with four stomachs instead of for a child with but one stomach. The protein of all milks coagulates in a form analogous to the future food of the adult animals.

Dr. J. Madison Taylor of Philadelphia said he had long held the opinion that one of the most essential points in the artificial feeding of infants was to get the milk as fresh as possible and use it as soon as possible. By getting the milk directly from the cow and properly modifying it and using it as soon as possible, before its vital enzyme became dissipated, the speaker thought we were doing much towards the solution of this problem of infant feeding. It was entirely possible to have cow stables in cities similar to horse stables, yet with special equipment, including small open spaces for exercise. Portions of city parks could be used in this way, the stables being near by. Cows could be brought by automobile ambulances in an hour or two, and when dry returned in the same way. No one factor would contribute so much to save infant life as absolutely fresh milk accessible to those who needed it most.

Dr. H. Seymour Houghton spoke of certain cases of intestinal infection in children which were apparently the result of some peculiar form of toxemia, and which were

not associated with any prior inflammatory condition or due to bad feeding. This condition usually occurred in children who had been reared with the utmost care. The symptoms came on suddenly, like a thunder shower in summer, with or without preliminary fever and without diarrhea, but with constipation and stupor.

Dr. Walter Lester Carr said that intestinal infections might be of different varieties. For example, since the discovery of the Shiga bacillus many cases of summer diarrhea had been found to be due to this bacillus or to one of its associates, the Flexner or Hiss form. These cases of bacillary diarrhea were not always severe, nor were they dysenteric in the sense in which the word was formerly used. The term intestinal infection might designate also the complex changes found where there was incomplete metabolism—autointection. A common form of summer diarrhea might be dependent upon changes in cow's milk from faulty methods in handling. With clean, fresh milk, kept at a temperature of 45°, there was little danger of intestinal disease. It was an accepted fact that if babies were fed on breast milk, their natural food, they did not suffer from summer diarrhea, but as many babies were not able to get breast milk, the best that could be done for them was to use modified cow's milk.

Dr. William Shannon said he thought that many of the summer diarrheas in children could be prevented if we instructed the mothers how to handle the milk after its delivery in the morning. The milk was often left for an hour or more on the window sill or near the kitchen stove before it was put on the ice, and thus the growth of bacteria was favored. The speaker said he had seen many examples of the beneficial effect of the treatment outlined by Dr. Winters, whose success largely depended on the manner in which he impressed the parents to carry out his instructions to the letter.

Dr. William D. Tyrrell, discussing the etiological factors of intestinal infections in children, said we could not draw any hard and fast line between the chemical and bacteriological factors. Personally, he was convinced that an excess of protein in the food was often an exciting factor, as it always left a residuum in the large intestine which was acted on by the putretactive bacteria and formed an irritant. During the intense heat of July and August, when it required less feeding to maintain the body temperature, the babies received the same amount of food as during the cooler seasons, and so were overfed.

Dr. Winters, in closing the discussion, said that all he knew of intestinal derangements in children he had learned from dispensary or tenement-house practice. Even among the poorer classes the necessary amount of top milk could be obtained by making an arrangement with other tenants in the house, and he never had the slightest difficulty in having the mothers carry out his instructions. On the contrary, it was marvelous how exact and careful the mothers were when they were properly impressed with the importance of the matter, and when the instructions were given to them in written form. For this purpose, printed slips had been prepared, which gave the hours of feeding, the number of feedings, and the proper quantities; everything was written out. Speaking of the fat content of the food, Dr. Winters said that when diluted, the feedings as he recommended them were not excessive in fat. None of the milk delivered in New York City gave more than 25 per cent. of fat when the upper half ounce was used. In reply to Dr. Chapin's statement that every time we were putting cow's milk into a baby's stomach we were putting in a foreign body, Dr. Winters said that by taking the top half ounce from a quart bottle of milk and treating it as he had described we obtained a product that could not be told from woman's milk. We had to feed babies artificially, and the sooner we got away from this nonsensical biological talk the better.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of July 2, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	493	158
Diphtheria	371	26
Measles	623	20
Scarlet Fever	236	13
Smallpox	2	—
Varicella	95	—
Typhoid Fever	45	13
Whooping Cough	57	4
Cerebrospinal Meningitis	2	2
Malarial Fever	—	—
Totals	1,924	236

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended July 1, 1910.

THE PSYCHONEUROSES: AN INTERPRETATION.*

BY JOSEPH COLLINS, M.D.,

NEW YORK.

PHYSICIAN TO THE NEUROLOGICAL INSTITUTE OF NEW YORK.

MANKIND is liable to affliction with certain disorders that are called nervous diseases. When the nervous system thus diseased undergoes demonstrable structural alteration, the disease is said to be organic. When such alteration is not demonstrable, the disease is said, without prejudice, to be functional. Such functional nervous disease is called a neurosis, and when it is attended in its display with conspicuous mental and emotional symptoms, the name psychoneurosis is often and legitimately given to it.

Year by year our conception of disease changes. At one time it changes more rapidly in a certain branch of pathology; at another in quite a different branch. In neurology the changes are more striking and less convincing than in any other branch of medicine. This is so because the pathological physiology cannot be understood until the normal physiology has been established. The physiology of the brain, and to a lesser extent of the spinal cord and the sympathetic nervous system, is still an unfinished chapter. Until the functions of the nervous system are determined, the functional nervous diseases must remain somewhat enigmatic.

The chief functional nervous diseases or neuroses are epilepsy, migraine, tic, hysteria, neurasthenia, and psychasthenia. Epilepsy and migraine are not attended with mental and emotional symptoms. Tic may or may not be, but hysteria and neurasthenia are, and they are the psychoneuroses. Whether or not there are others depends upon what is meant by these designations.

What Is Hysteria and What Is Neurasthenia?—It is not an easy matter to define hysteria or neurasthenia, either in a conventional sense or in a medical sense, but, that any value may attach itself to a discussion of the psychoneuroses before a body of physicians interested in all human ailments it is necessary that an attempt be made to define them, or at least to state the significance accorded them by neurologists.

It is not so long ago, about 60 years, that all diseases of the nervous system were classified as functional diseases, neuroses. Then, in one generation, thanks to the initiative of Duchenne in France and Romberg in Germany, many of them yielded the secret of their existence. The beginning of the present century saw still included in this category chorea, paralysis agitans, and exophthalmic goiter. They have now been removed, and year by year the list of functional diseases grows smaller; and there are some who incline to believe that eventually it will include only the psychoneuroses; that epilepsy, migraine, and tic will be found to be dependent upon demonstrable lesion and that the visceral neuroses will reveal a genetic relationship to obsession.

The Trend of the Times Is Toward Simplicity of Classification.—Be that as it may, certainly the trend of the times in Neurology and in Psychiatry is toward simplicity of classification and the grouping together of cases which, though they may vary widely in their symptomatic manifestations, have fundamentally certain characteristics in common. Thus hysteria, neurasthenia, psychasthenia, states of mental and emotional unrest under the dominion of obsession or fear, states of anxiety and of panic, are classified as psychoneuroses. The essential factor in all of them is psychical, and as we approach the last analysis, we shall see that it is ideo-obsessive.

The Designation Hysteria Often Misapplied.—Many designations in medicine are used loosely. Hysteria is one of them. Indeed, it is the most flagrant example. No one believes at the present day that hysteria has anything to do with uterus, but it is probable that few of us have the same mental picture called up by this designation. Hysteria is a disease which manifests itself by fairly well-defined symptoms, though they vary enormously in intenstiy and in association. They may be so slight as to cause merely inconvenience, or so overpowering as completely to incapacitate. We are very familiar with its clinical manifestations and with its career. We know something of its causation, in so much as we know that it may be called into existence by fright or by forces designated as moral shock. We know little or nothing of its pathology, and our theories of its causation now, just as since time immemorial, are not susceptible of proof. Whether they are more tenable than those which they attempt to dislodge, depends upon the point of view.

The Theories of Hysteria.—The newest theories of pathogenesis of hysteria are those advocated by Babinski of Paris, and of Freud of Vienna. For Babinski, hysteria is a special psychic state manifesting itself principally in disturbances which are called primary, and subsequently in secondary disturbances. The primary disturbances are distinguished by the fact that it is possible to reproduce them by suggestion in certain subjects with rigorous exactitude and to cause them to disappear under the exclusive influence of persuasion. The secondary disturbances are distinguished by the fact that they are immediately subordinate to the primary disturbances.

Babinski proposes to call hysteria pithiatism, because it is susceptible of cure by persuasion. In

*Read before the Canadian Medical Association, Toronto, June 2, 1910.

fact, he seems to think that it is the only neurosis that is susceptible of cure in this fashion! He denies that the so-called signs of hysteria are characteristic or permanent, or that they have the fundamental importance that has been attributed to them. Although a number of years have elapsed since Babinski's views were first submitted to the profession, it is not apparent that they have been widely accepted, nor has the term pithiatism come into use.

The chief service of the discussion provoked by the advocacy of this theory has been to show that many of the so-called stigmata of hysteria, *i.e.* the objective signs, have been given a fictitious value by French writers, and that many of the symptoms of major hysteria existed in the imagination of the person describing them, or are instances of association of hysteria and organic diseases "badly interpreted."

Freud's Theory.—The theory of Freud cannot be so summarily dismissed. Originally formulated by Breuer and Freud it is in reality an extension of doctrine propounded by Janet, which holds that hysteria is a psychosis belonging to a group of mental diseases due to cerebral insufficiency. It is characterized especially by moral symptoms. The essential feature is weakening of the faculty of psychological synthesis. The hysterical process causes a splitting, a disintegration, a doubling of personality. Freud adopts this theory and contends that the disintegration is initiated by a force which he calls sexual trauma. In order that I may do him no injustice, I quote literally the conclusion of his chief disciple and advocate, Jung. "There develops usually on a constitutional basis before puberty definite sexual activities which are chiefly of a perverse nature. These activities do not as a rule lead to a definite neurosis before the time of puberty, which, by the way, manifests itself earlier in the psyche than in the soma, but to sexual phantasy, which takes on a perverse, constellated direction by reason of the infantile sexual activities. On constitutional grounds the increased phantasy of the hysterical individual leads to the formation of complexes which are not taken up by the personality because of the shame and disgust which they engender. They remain buried, and thus is initiated a conflict between normal passion (libido) and the sexual representation of these buried infantile perversions. This conflict gives rise to the symptoms of hysteria.

The Mechanism of Hysteria.—Freud explains the mechanism of hysteria as follows: Experiences of a painful emotional character are psychic traumata, and if not reacted to adequately and appropriately they remain in the mind and give rise to affect-memories. If these affect-memories are sufficiently organized they may usurp control of the bodily innervation as well as the psychic activity, thus producing various hysterical phenomena.

The psychic trauma may consist of a single experience, or of a group of experiences, or it may result from indifferent occurrences coinciding with a time of special nervous susceptibility as in a state of fear. The connection between the psychic trauma and the resulting phenomena may be obscure. Often it is forgotten and frequently it is unpleasant to relate.

The affect-memory may produce (1) a single acute attack of hysteria, (2) a series of more or less persistent symptoms of a hysterical nature, or, more frequently, (3) a combination of these two. Hysterical attacks may be spontaneous or provoked either directly by recalling the affect-memory or indirectly through some experience analagous to that which caused the trauma.

Normally, the memory of any event fades with the passing of time, but this takes place only when the individual reacts adequately to the experience. Speech alone may be sufficient to facilitate the reaction or it may require voluntary or involuntary reflexes, from weeping to an act of vengeance. Adequate reaction may be prevented (a) by experiences to which no reaction is possible, as the death of a beloved one, and (b) by experiences which the individual voluntarily excludes from the field of consciousness as in sexual matters, or (c) they may be prevented by the nature of the attending circumstances, such as experiences accompanying fear or occurring under abnormal conditions such as revery-autohypnosis.

The phenomena of dissociation are analagous to those of dreams in which the experiences are detached from the normal consciousness. Freud calls this the hypnoidal state. Dreams do not influence the waking state while the products of the hypnoidal condition obtrude themselves into waking life as hysterical phenomena.

Even in a normal person, a severe psychic trauma, or a forced suppression of an affect, brings about a splitting off of groups of ideas, but in time these are assimilated and the memory fades away. In hysterical subjects, the splitting-off group remains split-off and long retains its original vividness. A series of hypnoidal memories may associate with each other and reach a high degree of psychical organization even to the highly organized "second personality." Each hysterical attack acts as an additional trauma, reinforcing the tendency to subsequent attacks. The two physical conditions, *i.e.* the normal consciousness and the hypnoidal consciousness, tend to establish a system of alternating activity which admits of each assuming control without really influencing each other.

Criticism of Freud's Contention.—Freud takes an attitude toward consciousness such as one would take toward a working machine, and proceeds to describe it in terms of what he calls psychic mechanisms. His procedure is not systematic, and he omits to give any extended description of the psychic mechanism of the normal mind except by implication. What he has to say concerning this has to be gathered mainly from his description of what occurs to the normal mind at certain "critical moments," by which he seems to mean moments when under severe stress, possibly accentuated by some fundamental lack of staying power in the subject of this experience, the customary complete control of the situation is lost, and a situation is produced which is neither understandable nor removable, and which consequently remains in the active consciousness only as an obstructive element. If the mind is of good staying quality it will wrestle with the intruding state until it interprets its meaning, in terms of its larger and less stressful experience, and so brings it under control. If it fails to do this it suffers the inconvenience of having the process repeated until there is sufficient of this material on hand to call for organization unto more complex systems of activities. These symptoms never get related to the main activities of consciousness, no matter how far this secondary organization proceeds.

Freud's general method of treating his subject, then, is to take up a certain attitude toward the normal mind, to proceed from that to an abnormal condition of it which he calls traumatic, from which he is ready to advance another step to the phase of abnormality known as hysteria.

No particular objection can be raised either to an attempt at mere description, or to this order of procedure. It is only when the details of his effort are scrutinized that its limitations appear. Even these are of negligible importance, unless it can be shown that the resulting description is, by its very nature, a doubtful foundation on which to rest the principles of treatment of hysteria.

Freud's interpretation of hysterical states should therefore be subject to severe scrutiny in the matter of details, for it is there that the insufficient or misleading nature of the process will make itself apparent.

Two tests might be applied to the working out of his method. One would be seriously to accept his view of the mind as a mechanical structure, and attempt to complete his sketchy outline according to the implications he makes, and then to criticise the description in the light of its total result. A much simpler way is to try to make the most of the situation as he outlines it, allowing for the insufficiency of the terms, frankly discounting their significance as anything more than merest connecting material and resolutely avoiding an extension of fictitious values.

Among the terms which Freud uses with great freedom and with no open acknowledgment of their fictitious values are: Traumatic neuroses, psychic trauma, causal trauma, grand trauma, partial trauma, affects, affects of memory, affective ideas, affectful experience, abreactions, cathartic reactions, psychic determinants, associative elaborations, associative organizations, hypnoid states, hypnoid ideation, hypnotized memory, accidental moments, etc. Furnished with this set of terms, which he dignifies by describing them as psychic mechanisms, and with the general conception of this mind as a working machine, he proceeds to weave together his picture of hysteria with alluring ease and certainty. There is first the normal mind, which makes its complicated adjustments to situations, shaping the mechanical parts and grouping them into sufficiently organized activities to meet the ordinary situation of experience. It takes, that is, a certain attitude of its own contrivance toward the present situations, according to the way in which the situations affect it; these are affect attitudes on the part of the mental mechanism. Their peculiar significance is shown by the persistency of this affective element in the memory of the event; the slightest clue as to the original situation may bring back the full affect of the first experience.

Next there comes into view the normal mind, strained to its utmost, and reaching the breaking point, either because of the extraordinary nature of the event, or the inherent limitations of its mechanism; the result is a failure to complete the process of response. The mechanism is over-affected by the experience and responds partially and inadequately, instead of reacting in a fully organized and effective manner. Its abreaction is insufficient for the occasion, and below the capacity with which it is normally credited. Not the mechanism, so much as its habit of acting, has received an injury, a trauma. Inasmuch as it is a habit-forming mechanism, its condition is more or less permanently affected and may now be viewed as traumatic; that is, it is in a peculiarly susceptible condition toward a recurrence of a like event, which may cause a repetition of failure even though the situation is much less important than the original one. It is also generally susceptible toward the acquisition of traumatic experiences. The evidence of this new situation is very marked when we turn again to the activity of memory, into which this new class of representations has been introduced, and contends with normal memories on terms of even greater advantage than those which belong to the truncated experiences in their rivalry with completely organized experiences. The course of development which ensues for the normal mind depends on circumstances. If the extraordinary events are infrequent, and if the mind is of good sustaining power, no significant damage results, and the effect wears away or it is accommodated without serious disturbance of satisfaction.

Quite a different course of development follows in the case of minds that by the effect produced on them must be called in relative terms abnormal. The traumatic interruptions are more severe and lasting; the isolation of the peculiar memories resulting from the painful experience is more complete; their appearance as rival activities in the field of memory is more frequent and effective; the tendency to inaugurate new experiences of this sort is more pronounced. But with all this distortion of the mechanical activity one important feature of memory still remains, so long as memory itself is active: the association type of activity still persists and operates in the field of the isolated and secondary activities as well as in the immediately useful primary activities. As a result, there grows up in the abnormal mind, constituting its abnormality, a second set of organized memories which rivals the first set both in its power to affect new experiences as they arise, and in their capacity for organization about a second center.

Having reached this point, Freud has entered the field of hysteria as he conceives it. It is marked by nothing different in kind from what happens occasionally to normal minds, or to the abnormal mind more frequently on account of its greater susceptibility; but it is subject to become habitual and is marked by a tendency to continued organization of the useless activities into a complex which has no more important function to perform than to occupy the field of consciousness to the exclusion of the higher useful activities, and in a mischievous relation to the super-excitable motor activities which are no longer coordinated in some purposeful undertaking.

Dreams and Their Interpretation.—One of the aspects of the hysterical mode of mechanical activity to which he gives particular attention is the type of memories which originate in dreams, reveries, hypnoidal states. They belong in the class of free-flowing movements of the normal mind, which occur in greater frequency in ungoverned minds, and are the characteristic remainder in the suppressed form of mental activity called the hypnotic state. In the case of the hysterical mind, with its organized duplicity of behavior, and its consequent superficiality of movement, these free occurrences attain a significance they would not otherwise have. The memory of them becomes peculiarly intrusive, since the dissociation of mental activities into groups appears in its most pronounced form in the field of memory. The limitations of

the point of view which furnishes this description are apparent when it comes to its application to specific situations. As Freud himself is forced to acknowledge, the only method afforded is to go patiently over the field, pick up the traumatic occasions one by one, often in the most painful fashion, furnish the subject with a complete description of what he did and what he ought to have done—that is, to substitute a normal affect and a normal abreaction, and thus to dissipate the efficiency of the traumatic memory by withdrawing it from its dissociation from the normal associative process. It remains extremely doubtful how much of this training must be given before the hysterically disposed will have changed his disposition. It is certain that the mere removal of the uncorrelated memory will not do it, nor will voiding the effects of such an activity alter the native disposition of the subject. The indications are strong that isolation of the subject in a special environment is essential in order that no more false experiences may be set up. There are equally strong indications that the question of the economic importance of the process should be investigated in the case of each subject.

The objections to Freud's theory and practice are that his mode of interpretation is too arbitrary, that the psychoanalysis becomes a source of suggestion, direct and indirect, and that it gives a conspicuousness to the sexual factor as a causative agency which it has not yet been proven to have.

The arbitrary interpretation refers particularly to the dream symbolism, according to which theory dreams are psychical structures of sexual origin not always accessible to interpretation. The sense of any dream is the fulfillment of a wish; that is, dreams are the accomplishment of suppressed desires. Dream fabrics are characterized by a tendency to condensation and a displacement of the subconscious thought. This is the keynote for the translation of the hidden dream fabrics, and the attributed condensation resulting therefrom seem to me grossly exaggerated. The most serious objection, however, to Freud's procedure is that it becomes a source of autosuggestion. Psychoanalysis is equivalent to sexual analysis and every step in it turns on an erotic pivot. Only the completest self-mastery on the part of the interlocutor, and the supremest impersonality on the part of the victim can keep the element of autosuggestion out of the psychoanalytic seance. The constant digging for complexes becomes an enormous incentive to the individual whose mind and emotions are easily swerved to fabricate such complexes.

Even addmitting that sexual factors have the importance in the psychogenesis of hysteria that Freud maintains, very little has yet been vouchsafed us upon which to base the belief that the psychoanalysis is a reliable therapeutic agency.

If the most we can do for those afflicted with hysteria in the present state of ignorance as to its causes is to put them in possession of a description of their condition, then the service rendered them is of doubtful value if the description itself is artificial, strained, inadequate, or questionable.

Estimate of the Value of Freud's Hypothesis.—On the whole, it must be said that Freud's method justifies itself if it is not taken too seriously, and too much is not hoped for from its application. The specious appearance given to this statement through his use of analogical terms is easily "abreacted from" and need result in no distortion of view in the normal mind, free from superesthetic tendencies and hyperexcitability. It will undoubtedly work best with minds which are inclined to split up analytically and is most easily applied to minds whose difficulties have arisen through confinement of their marked experiences to the field of sex excitements, which are the most frequent highly developed crises to which the generality of people are subject.

What Hysteria Means to the Average Mind.—To the average student of medicine who has no theory of his own to explain hysteria, it is a disease founded upon a constitutional peculiarity which we speak of as neuropathic temperament or degeneracy, which is a matter of heredity, whose manifestations are frequently called into evidence by such forces as mental and emotional shock, which includes fear, worry, grief, anxiety, and physical injury or disease. This hypothesis interprets the manifestations of hysteria as the persistence in adult life of childish types of reaction to the facts of life. The hysterical reaction is in reality an attempt at adjustment to experience.

Neurasthenia a Mental Disorder.—In attempting to define neurasthenia, we find our task no easier than when we essay to define hysteria. We certainly do not mean what Beard meant when he first described it or when he finished describing it. "Exhaustion of the nervous system, the effect of wasting fevers, exhausting wounds, parturition, protracted confinement, dyspepsia, phthisis, Bright's disease, etc.; a part of the compensation for our progress and refinement in civilized intellectual communities." It is no more a part of the compensation which we pay for our present-day culture and civilization than Christian Science or Spiritualism is. It is a manifestation of atavism that has not been corrected by education. Beard speculated that it was due to a change in the central nervous system. "The central nervous system becomes dephosphorized, or perhaps loses somewhat of the solid constituents; probably also undergoes slight indetectable, morbid changes in its chemical structure" (*Boston Medical and Surgical Journal*, April 29, 1869). This view that neurasthenia is the expression of some debilitating physical experience gained ground for 25 years. At the end of that time it was a clinical Colossus in the shape of a Sphinx. Nearly every "functional" nervous disorder unaccompanied by convulsion, profound suicidal impulse, or dementia, was placed beneath its covering. The first veil was lifted from its face by Dunin of Warsaw ("Grundsatze der Behandlung der Neurasthenie und Hysterie," Berlin, 1902), and in this country by Dana in 1904, who in that year read a paper before the Boston Society of Neurology and Psychiatry entitled "The Partial Passing of Neurasthenia" (*Boston Medical and Surgical Journal*, March 31, 1904), in which he pointed out that a large number of so-called neurasthenias should be classed as prodromal stages, abortive types, or shadowy imitations of the great psychoses. "The morbid mind dominates the situation, not a weak eye muscle, a poor stomach, a heavy womb, uric acid, arterial sclerosis, or even an exhausted motor nerve cell. The body also is at fault, but the psyche is in main control, and gives the stamp to the syndrome, directs the prognosis, and most acutely solicits the treatment."

That the mind in its perverse activity dominates the clinical picture presented by neurasthenics had been noted many times by innumerable investigators, but it has been impossible to dislodge from the

medical mind, and from the lay mind as well, the conviction that neurasthenia is the expression of physical disease, and that the problem which the neurasthenic patient presents is the detection of the disease or disorder of which the neurasthenia is merely an end-result, or an epiphenomenon. Therefore, the neurasthenic's digestion is attacked, his vascular system is treated, his eliminative pathways are stimulated, his sense-organs are tested and aided, his viscera are replaced, he is rested and fed and fattened and very properly so, if the sick person needs it, but when these infirmities are overcome the disease may still exist, its ravages for the time having been repaired. It has been with the greatest difficulty that the conception of neurasthenia as a disease and not as a symptom-complex indicative of some other disease has been forced upon our recognition. Another thing that has retarded our understanding of neurasthenia is that it has meant one thing for one person and another thing for another; in other words, it has had no definite clinical connotation. Under this category has been included all cases of nervous disorder that could not be readily classified. The custom has been if you do not know what it is, call it neurasthenia, so to the laity neurasthenia, or nervous prostration, has come to include a large part of the non-dementing insanities.

Almost from the beginning it was recognized that there was a form of neurasthenia which occurred in individuals with an inherited neuropathic temperament. From the time of Charcot this variety has been called hereditary or constitutional neurasthenia. About ten years ago Janet, recognizing that these so-called constitutional neurasthenics made up a considerable proportion of all the neurasthenics, proposed to set them apart and label them, which he did, and the name that he applied was psychasthenia. Since then, owing to Janet's continued interest in the study of these neurasthenias, and to the co-operation of Raymond, psychasthenia has become quite well known to the medical world and its coming has been heralded far and near. Many writers are already using it synonymously with neurasthenia without defining what they mean by neurasthenia. The result is added confusion.

Neurasthenia and Neurasthenic States.—The matter that we have first to decide before we can make any headway in this discussion is: Does the average individual—here spoken of as the normal individual—exposed to the attributed causes of neurasthenia, namely, work, worry, privation, and disease, develop a complex of symptoms which constitutes a fairly definite clinical picture whose leading features are fatigue, inertia, abulia, and perversion of function of the vegetative system. If he does, neurasthenia is a fatigue, a toxic, an exhaustion neurosis. The longer I practice medicine, and the more intimately I become apprised of the results of the activities of the above-mentioned agencies, the more am I convinced that neurasthenia does not flow from any of these causes. The normal man may work and overwork, the normal man may worry intemperately, the normal man may encounter disease in its most tempestuous or undermining way, the normal man may break all of hygeia's laws, and as the result of all these, he does not develop neurasthenia. He may become inert physically, sluggish mentally; he may have disturbances of all of the important functions of his body; he may have no initiative, and he may be depressed and dissatisfied with what has been meted out to him, but such an individual has some disease or disorder of which these symptoms are but expressions, and as soon as these diseases or disorders are overcome, the symptoms which are commonly labeled neurasthenia will vanish. If it facilitates the recognition and pathological dependency of such conditions to call them neurasthenia or neurasthenic states, I have no valid reason to give why they should not be so designated. The point I wish to make is that they do not constitute a disease *sui generis*, and that the symptoms are mere ancillæ of other diseases. I believe there is a disease which is properly called neurasthenia, that it is always a psychasthenia, and that it is a true psychoneurosis. It is a disorder characterized principally by lack of initiative and of executive capacity. Those who are afflicted with it, can neither start the ball of daily life nor can they keep it going when it is started for them. Physically they are tired and inert, mentally abulic and inactive. They are depressed, preoccupied with themselves and their infirmities, filled with foreboding, unable to accept assurance, their thought and conduct often under the dominion of an obsession or obsessive ideas. They have symptoms referable to every system of the body; one may predominate today, another to-morrow; but fundamentally the symptoms that are invariable are the mental and emotional symptoms that have been enumerated above.

This variety of neurasthenia flows apparently from overwork, disease, and dissipation, but only in those who have that something which we call neuropathic heritage. The neuropathic heritage cannot be defined with the same exactitude as a physical trauma, but every one knows what is meant when the term is used, just the same as every one knows when the term arthritic diathesis is used. Amongst other things that such an individual has is inability to resist physical and psychical influences which are not injurious to the average individual. These influences oftentimes causes a complex of symptoms to which we given the name neurasthenia or psychasthenia, and if the latter conveys more clearly both the origin and its clinical display, its course and its termination, then it may be used in preference to the other.

The majority of the cases diagnosticated as neurasthenia by the rank and file of us are not neurasthenic states nor neurasthenia. In the young they are dementia præcox, atypical attacks of manic-depressive insanity, and hysteria. In the mature, they are forms of mental involution, particularly melancholia.

Ten years ago the diagnosis of neurasthenia was very common in the Out-Patient Department of every hospital. Nowadays it is made with comparative rarity. The bodily disease which is attended with neurasthenic states is searched for, often detected, and properly designated, and no less often the mental disease masquerading as neurasthenia is made out. This leaves far fewer "neurasthenics" than our predecessors of a generation ago taught us to believe was the case.

Unity of Designation Desirable.—I said in the beginning that the psychoneuroses were hysteria and neurasthenia, or psychasthenia. If these include all the psychoneuroses we must enlarge our conception of them, and that probably is what we shall do. Three years ago Dr. G. L. Walton read a paper before the American Neurological Association, in which he pointed out that the majority of cases classified as neurasthenia,

psychasthenia, and phrenasthenia, partake so far of the various morbid mental states peculiar to the ideo-obsessive that they are best included under the general designation psychoneuroses or obsessive psychoses, and that is the conclusion that I have come to. If we could call all the various clinical complexes that are classified as functional nervous diseases, in which there is a dominant mental element, psychoneroses and the victims of such disease, psychoneurotics, it would be a great deal simpler than to call them neurasthenics, hysterics, psychosthenics, hypochondriacs, sufferers from obsession, doubting madness, counting mania, anxiety neuroses, etc.

As a matter of fact, nothing whatsoever is to be gained by an effort to classify these cases into separate disorders; the thing to be recognized is that fundamentally the disorder has its foundation in disordered mentality and emotivity, that the manifestations of the disease are immediately conditioned by obsession and that it is in reality an obsessive psychosis on a hereditary basis.

A word concerning the rôle that the psychoneuroses play in contributing to all the misery in the world. Only the neurologist who sees the psychoneurotic at short range can realize their relationship to incapacitating mental states and to unhappiness. Recognition of their existence, a conception of their construction and development is the best preparation that we can have to deal with them. Successfully to do so is a problem in orthogenesis which for its solution requires study of the laws of heredity and the principles of psychology by a person who loves his fellow man.

DUODENAL ALIMENTATION.*

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

As is well known, there are frequently conditions in which the usual methods of alimentation (by mouth and stomach) are either impossible or undesirable. Rectal feeding has always been used in these cases before. Every clinician, however, knows how unsatisfactory this mode of nutrition is. The food is utilized only in a small degree, and, besides, the rectum often becomes irritable, so that the enemata must be stopped. It is therefore desirable to have some other way of feeding to the exclusion of the stomach.

The duodenal pump,† which usually serves the purpose of obtaining the duodenal contents, can also be used for the introduction of food into the duodenum. This kind of feeding may be designated as "duodenal alimentation." The method consists simply in introducing the duodenal pump into the digestive tract, and feeding is begun as soon as its end is in the duodenum. The apparatus is left in the digestive system for from 8 to 12 days. The thin rubber tube does not inconvenience the patient, and thus everything is ready for the feeding. This is best done at intervals of two hours. After the feeding, water is forced through the tube, and finally air blown through and the stop cock is closed. We can introduce at one feeding between 240 to 300 c.c. of food slowly. All fluids must, of course, be used at body temperature. I have used this method of treatment successfully in three cases.

Usually the following nutritive material was used every two hours, from seven in the morning until nine in the evening: Milk, 240 c.c.; 1 raw egg, sugar of milk, 15 Gm. The mixture well beaten up

Fig. 1.—Patient being fed through the duodenum.

and injected at blood temperature. Patient received nothing by mouth. Two patients were given, besides, a quart of physiological salt solution by rectum, according to the Murphy drop method; the third patient also received water directly injected into the duodenum, but very slowly, drop by drop. I would like to append a photograph of a patient who is just being fed according to this method. (See Figure 1.) I will now briefly outline the three cases treated according to this method:

Case I.—January 29, 1910. Dr. L. A. S., 42 years old, suffered since his seventh year from

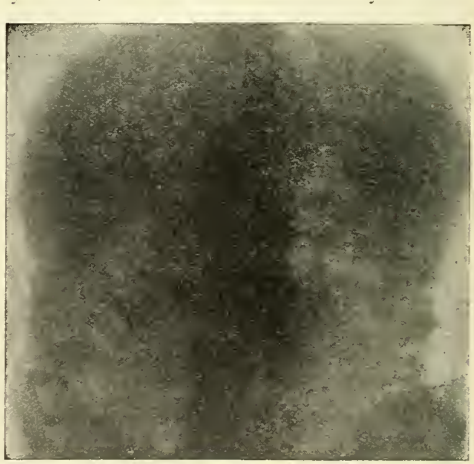

Fig. 2.—X-ray photograph of patient, Dr. Sh. with the duodenal pump in the digestive tract. The tube is seen along the whole course of the duodenal loop and the capsule in the beginning of the small intestine.

migraine. An error of refraction was corrected with glasses, and his condition was considerably improved, without, however, entirely relieving him. For the last ten years patient suffered off and on from attacks of vertigo, followed by intense headaches, with subsequent vomiting. The vomited matter consisted mainly of a sour liquid, mixed with bile. The attack generally lasted a few hours, and seemed to recur about every 2 or 3 weeks with-

†Einhorn, Max: Medical Record, January 15, 1910.

out apparent cause. Immediately after the attack patient would feel perfectly well. Occasionally he would not have an attack for from one to two years.

Lately, however, the attacks became somewhat more intense. They lasted longer, and were of a more severe character. The present attack began three weeks ago, with the usual vertigo, followed by headache and vomiting. Patient feeling easier after the attack, and being very busy, he did not take the necessary rest, and in consequence thereof he soon had a second attack. After partaking of milk and toast, he had considerable nausea and eructation of gas. Twelve hours later patient took kumyss. This patient retained, but soon headache, vertigo, and belching occurred. This condition lasting for six days, without any signs of improvement, patient entered the hospital, after having lost twenty pounds.

Present condition: The patient looks very weak and pale. The thoracic organs reveal nothing abnormal. Palpation of the abdomen shows marked tenderness over the epigastrium. A splashing sound can only be elicited with difficulty. According to this, the stomach reaches to about the level of the navel. The spleen is markedly enlarged and easily palpable; temperature normal, urine negative.

The patient was examined by means of the duodenal bucket. It was left in the digestive tract over night, and was removed in the fasting condition. There was no resistance to be felt at the pylorus, and the thread showed no bile discoloration, but a brown spot at 48 cm. Apparently the bucket had remained in the stomach without passing the pylorus.

Lavage of the stomach in the fasting condition shows food remnants from the day before and an acidity of 110, with an excess of HCl; occult blood was present. The duodenal bucket was then used a second time. This time, on withdrawing the bucket, a slight resistance was encountered at the pylorus. The thread was of a golden yellow color near the bucket, and again showed brown discoloration at 47 to 48 cm. The diagnosis was made of migraine, ulcer of the stomach, with recurring spastic stenosis of the pylorus and enlargement of the spleen. As patient vomited continually, rectal feeding was ordered. Patient, however, could not retain the nutritive enemata and they had to be stopped.

On Feb. 2 the duodenal pump was introduced.

Fig. 3.—X-ray photograph of patient McC. The tube of the duodenal pump is visible in the duodenal loop and in a considerable part of the small intestine. The stomach was filled with air by means of a thin stomach tube, and is seen as a light zone. Owing to the bismuth medication, the colon is also visible.

After about two or three hours it had reached the duodenum. (This was proved by aspirating the duodenal contents, which reacted alkaline and contained all the pancreatic ferments, as well as bile. See Figure 2.) The duodenal pump was left in, and patient nourished through it. Every two hours either milk alone, or milk and egg with sugar of milk in 8-ounce quantities, were slowly injected into

the duodenum by means of a syringe. Patient soon felt better; the feeling of hunger disappeared, and with it that of weakness. The vomiting stopped. The duodenal feeding was continued for eleven days. During this time patient gained one-half pound.

At the end of this duodenal feeding period (Feb. 13) the duodenal pump was removed, and the usual oral feeding was again begun. Soon patient again suffered from gastric disturbance, marked by acidity and the belching of much gas.

An attempt was made to dilate the pylorus through the introduction of an inflatable pyloro-dilator. This was successful once. A few days later, however, on my desiring to repeat this procedure, the instrument did not pass the pylorus.

Patient left the hospital and to-day (April 6, 1910) is not free from his complaint.

Case II.—Jan. 29, 1910. Wm. M. McC., 21 years old, is complaining for two or three years of his digestion. He is constipated, and feels a sensation of distress about one-half hour after meals, lasting for one and a half hours. At the same time, mental depression, vertigo, a desire to rest, and a feeling of complete physical exhaustion occur. This state would last a few days, and increase in severity until patient took either a laxative or violent exercise, which generally resulted in improvement for one week, when it would recur again. The attacks increased in severity, patient was very nervous and began to have hallucinations. These occurred only after meals, and disappeared when patient brought up gas from the stomach. Patient had lost 15 pounds in weight.

Physical examination shows that the heart dullness begins at the lower border of the fourth rib. There is also ptosis of the liver. The right kidney is movable in the fourth degree. The stomach is considerably dilated and reaches a hand's width below the naval. The urine showed nothing abnormal; pulse small; temperature subnormal. Examination of the stomach contents one hour after Ewald's test breakfast shows: HCl + Acidity = 74, some food remnants from the day before. In the fasting condition the stomach also contains a small quantity of food from the previous day. The duodenal bucket, which on the second of February was left in the digestive tract over night, and was removed in the morning in the fasting condition, showed a discoloration due to bile from the bucket up to 65 to 61 cm., and a brown discoloration from 59 cm. to 61 cm. The rest of the thread was white. The diagnosis was made of enteroptosis (cardioptosis, hepatoptosis, right movable kidney) and duodenal ulcer with dilatation of the stomach and slight ischochymia, probably caused by pylorospasm.

Patient was placed on duodenal feeding on February 4. The duodenal pump easily reached the duodenum (within one hour). All feeding per os was discontinued, and only duodenal feeding was resorted to. The length of the rubber tube was 85 cm., so that the capsule laid in the small intestine. (See Figure 3.) Every two hours he was given either 8 ounces of milk, + half an ounce of sugar of milk, or the same with the addition of a raw egg well beaten up. Besides this, patient received a quart of physiological salt solution in divided doses injected through the tube directly into the duodenum. Every other evening an oil enema of 8 ounces was given.

As medication he received magnesia usta, 3ʒ½ bismuth subnitrate 3ʒ, water 3ʒ; one tablespoonful three times daily by mouth. The mouth was frequently washed with a weak solution of tincture of myrrh. Patient was treated in this manner for nine days. Then I began to give small quantities of fluid by mouth in addition to the duodenal feeding. On the tenth day the duodenal pump was removed (Feb. 14), and patient was nourished by the mouth. He was first given five ounces of fluid food every two hours, which was quickly increased to eight ounces, and then ten ounces.

A new test with the duodenal bucket on Feb. 20 showed a greenish discoloration due to bile at 60 to 70 cm.; no brown spot, however, and the remainder of the thread was white. (See Figure 4.)

The patient was then given a more ample diet, and his stomach was irrigated off and on in the fasting condition. It was now always found empty. On April 4, 1910, the patient reports that he has gained ten pounds in flesh and has no more trouble. Physical examination shows that the heart and liver lie normally. The right kidney cannot be palpated, and the stomach reaches only to the navel. It seems that we have to deal here with the cure of a duodenal ulcer and the restitution to the normal of an enteropotosis of a high degree.

Case III.—Mrs. Josephine R., 39 years old, began to suffer from digestive disturbances three years ago, accompanied by violent headaches and vomiting. A year ago she had abdominal colic. She was operated in the Roosevelt Hospital, and her appendix removed. This operation, not proving successful, patient was operated at another hospital in 1909 for adhesions. She then felt fairly well for two months. Soon, however, the old pains returned and uncontrollable vomiting set in, for which she was admitted to the German Hospital.

Physical examination does not reveal anything abnormal in the thorax. In the abdomen there is slight tenderness on pressure over the epigastrium. The stomach extends two finger widths below the navel. A test meal shows absence of HCl, and an acidity of = 20. The urine—daily amount of which varies between 300 to 1750 c.c. for 24 hours—shows a trace of albumen; otherwise nothing abnormal. The duodenal bucket showed that the pylorus was open. Neither were there any blood spots on the thread. Patient complains of constant vomiting, not being able to retain even water. A diagnosis of subacidity and nervous vomiting was made. The usual treatment was instituted, but without success.

On March 22 duodenal feeding was resorted to. Patient received every two hours eight ounces of milk, one egg, and half an ounce of sugar of milk, well beaten up, through the duodenal pump. This was given eight times daily. Besides this, she was given a quart of physiological salt solution, per rectum, according to the Murphy drop method. The treatment was continued until April 2.

During this period she had vomited only rarely, not, however, food, but small quantities of a watery fluid, mixed with mucus. The patient felt well, had no hunger nor thirst, and looked well nourished. Her weight remained nearly stationary. It was as follows: March 23, 140 pounds; March 26, 142½ pounds; March 28, 140 pounds; March 31, 140½ pounds; April 1, 139 pounds. Pulse and temperature were normal, her stool was formed.

After resuming feeding by the mouth the vomiting recurred. She will probably soon have to again be fed by the duodenum.

None of the three cases lost any appreciable

weight during the duodenal feeding. They felt very well, *i.e.* the feeling of hunger was satisfied, and while without food they felt weak and tired, they felt well and strong after the duodenal feeding. At all events, the cases prove that good nutrition may be kept up (without loss of weight) for a longer period, without stomach feeding.

The advantages of duodenal over rectal feeding are at once apparent; for while the rectum and colon are simply organs for the expulsion of fæces and for the absorption of possibly remaining liquids, we have to deal in the duodenum with an organ where the most important digestive juices are secreted.

In the colon we have to do with the last part of the digestive tract, in the duodenum, however, with the principal part of the digestive appartus, so that everything is here utilized.

THE DIAGNOSIS OF SUPPURATIVE DISEASE OF THE NASAL ACCESSORY SINUSES.*

By ALFRED BRAUN, M.D.,

NEW YORK.

ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

An absolutely essential requisite in making an intelligent examination of the nasal accessory sinuses, is a thorough knowledge of the anatomy of these cavities. A few of the chief points in their structure and relationships will, therefore, not be amiss. There are four cavities on each side of the head, the frontal, ethmoidal, maxillary, and sphenoidal cavities. The frontal and sphenoidal are confined to a single bone each, while the maxillary and ethmoidal sinuses have several bones entering into their formation, the ethmoidal cells being enclosed by the ethmoid, frontal, lacrymal, and sphenoid bones, while the maxillary sinus has entering into its construction the superior maxilla, ethmoid, palate bone, inferior turbinate, and lacrymal bones.

The largest of these cavities is the maxillary sinus, or antrum of Highmore (Fig. 1).

Fig. 1.—FS. Frontal sinus. E. Ethmoidal cells. A. Antrum of Highmore. O. Orbit. OF. Olfactory fissure. MM. Middle meatus. IM. Inferior meatus. U. Unciform process. OA. Ostium antri. CG. Crista galli. MT. Middle turbinate. IT. Inferior turbinate.

This is a pyramidal cavity lying in the superior maxilla. The base is above, and corresponds to the floor of the orbit. The anterior is the facial wall, the internal corresponds to the outer wall of the nasal fossa, and the posterior looks toward the zygomatic fossa. The apex is directed downward, and lies over the roots of the bicuspid and molar teeth. Sometimes the roots of one or more teeth lie free in this cavity. Sometimes they are separated from the floor of the cavity by a layer of bone three-quarters of an inch thick. The normal orifice lies in the upper part of the nasal wall, a short distance below the roof of the cavity. The most important of these walls, from the viewpoint of diagnosis, is the inner or nasoantral wall. This wall is composed mainly of superior maxilla. The inner wall of the superior maxilla shows a large defect, which is partly closed in by inferior turbinate below, unciform process of the ethmoid above lacrymal bone in front, and palate bone behind (Fig. 2).

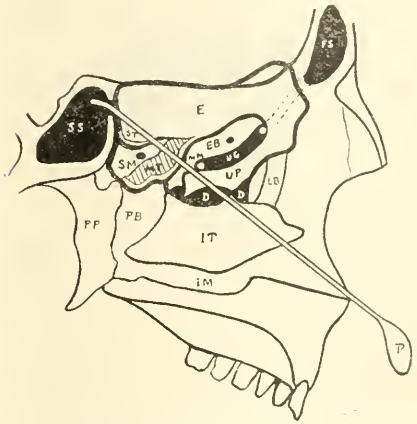

Fig. 2.—FS. Frontal sinus. SS. Sphenoidal sinus. E. Ethmoid bone. PB. Palate bone. PP. Pterygoid process of sphenoid. IT. Inferior turbinate. MT. Stump of middle turbinate. ST. Superior turbinate. LB. Lacrymal bone. IM. Inferior meatus. MM. Middle meatus. SM. Superior meatus. UP. Uneiform process of ethmoid bone. UG. Unciform groove or hiatus semilunaris. D. Defects in bony naso. antral wall. EB. Ethmoidal bulla. P. Probe in sphenoidal sinus. (Ethmoidal bone is drawn in with heavy lines.)

However, there is still left a small defect between the unciform process and the insertion of the inferior turbinate bone, and another small defect above the unciform process. The latter space is the site of the normal orifice of the antrum, while the former is filled in by mucous membrane, and is occasionally the site of accessory foramina into the antrum. The membranous portion is the weakest part of the nasoantral wall, and would be the ideal site for exploratory puncture, if it were

not for certain anomalies, which will be mentioned later on.

The ethmoid cells are enclosed entirely in the ethmoid bone, except the upper lateral and upper anterior edges, which are closed in by the ethmoidal notch in the horizontal plate of the frontal bone

Fig. 4.—(After Sieur & Jacob.) FS. Frontal sinus. OP. Its orbital prolongation extending backward as far as the posterior extremity of the ethmoidal cells. EC. Ethmoid cells. CP. Coibriform plate.

and the lacrymal bone; and the posterior surface, which is closed in by the body of the sphenoid.

The ethmoidal labyrinth consists of an irregular collection of cells enclosed in a quadrilateral box, situated between the orbit and the upper or olfactory portion of the nasal fossa. This box is formed externally by the os planum, internally by the superior and middle turbinates and superior meatus, below by the middle meatus, and above by the quadrilateral plate of bone which lies just external to the cribriform plate, and not as described by many writers, by the cribriform plate itself; in front by the lacrymal bone, and horizontal plate of the frontal, and behind by the body of the sphenoid (Figs. 1 and 2).

Sometimes there are dehiscences in the os planum, a condition which predisposes to orbital cellulitis and emphysema.

The ethmoidal cells are divided into two groups, an anterior and a posterior, dependent not upon their location, but upon the location of their orifices. The anterior group opens into the middle meatus of the nose, and the posterior, into the superior meatus.

In order to get a clear conception of the structure of the ethmoidal labyrinth, we will follow the description given by Hajek. He describes the ethmoidal labyrinth as being composed of cells which lie in three grooves, these grooves being separated from each other by four lamellæ of bone, which traverse the labyrinth obliquely, and are attached externally to the os planum, and above to the base of the skull (Fig. 3).

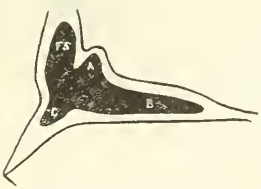

Fig. 5.—(Modified after Sieur & Jacob.) FS. Frontal sinus. A. Prolongation into crista galli. B. Orbital prolongation. C. Prolongation into root of nose.

These lamellæ are all complete except the first one, which does not reach up to the base of the skull. The first of these lamellæ is the unciform process of the ethmoid. This is a thin hook-shaped process of bone (Figs. 2 and 3), which is attached to the anterior inferior angle of the lateral mass of the ethmoid, and extends downward and backward for about an inch, where it ends free. This process forms the lower boundary of a groove, called the unciform groove, or hiatus semilunaris. This groove is of the utmost importance, both for the diagnosis and the pathology of accessory sinus disease, as it contains the orifices of the frontal, maxillary, and anterior ethmoidal cells, and obstructions in this groove will interfere with the drainage of these sinuses. The second lamella is the lamella of the ethmoidal buula, which begins at the upper anterior angle of the body of the ethmoid bone, and extends downward and backward to the posterior extremity of the lamella of the unciform process. This lamella contains the bulla cells, which are the most important factors in causing obstruction of the nasofrontal duct, and which must be removed in order to drain the frontal sinus properly. One of these bulla cells sometimes causes a prominence on the posterior wall of the frontal sinus, and is then called a frontal bulla. The third lamella is formed by the root of the middle turbinated bone, and the fourth by the superior turbinate.

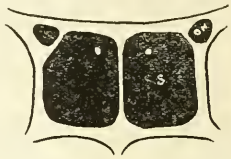

Fig. 6.—(After Hajek.) SS. Sphenoidal sinus with its ostium, viewed from behind. ON. Optic nerve.

The first groove lies between the unciform process and the bulla lamella, and consists of the unciform groove. The second groove lies between the bulla lamella and the lamella of the middle turbinate. It forms the middle meatus, and contains all the remainder of the anterior ethmoidal cells, outside of the bulla cells. The third groove lies between the lamellæ of the middle and superior turbinates. It forms the superior meatus, and contains the posterior ethmoidal cells. There are usually some posterior ethmoidal cells situated above the fourth lamella.

The anterior ethmoidal cells may open by a common orifice into the middle meatus, or each cell may have its own orifice. The posterior ethmoidal cells open by one or several orifices into the superior meatus.

The frontal sinus lies in the vertical portion of the frontal bone, between its anterior and posterior plates, sometimes extending back into the horizontal portion, above the inner angle of the orbit (Fig. 4). It is separated from the sinus of the opposite side by a vertical septum, which may be situated a considerable distance to one or the other side of the median line, so that one frontal sinus may extend over both orbita. The orifice of the frontal sinus is situated at its lowermost point. It opens into the nasofrontal duct, which is continuous with the unciform groove at its upper end. Obstruction to drainage of the frontal sinus may be located in the ostium or nasofrontal duct, due to swelling of its mucous membrane, but is more commonly due to hypertrophies in the middle

meatus or disease in the anterior ethmoidal cells causing an obstruction in the unciform groove.

In some cases there is no frontal sinus present in the vertical portion of the frontal bone. It is not absent in these cases, but is present as a small cell, resembling an ethmoidal cell (which it really is developmentally), located just above the lacrymal bone. In this situation it can only be reached through the orbital roof. The frontal sinus sometimes sends prolongations backward over the roof of the orbit, upward and backward into the crista galli, and downward and forward into the root of the nose (Fig. 5). The orbital prolongation is of considerable pathological importance, because in order to drain this properly it is necessary to remove a large portion of the roof of the orbit.

Fig. 8.—(Schematic after Onodi.) PEC. Posterior ethmoidal cells. ON. Optic nerve in close relation to posterior ethmoidal cell. S. Anterior surface of sphenoid, with its ostium. A. Antrum of Highmore. ST. Superior turbinate. MT. Middle turbinate. IT. Inferior turbinate.

The sphenoidal sinus is a quadrilateral cavity in the body of the sphenoid bone. The roof and posterior walls are in relation to the cranial cavity (Fig. 2). The roof is very thin and can easily be perforated in curetting the sinus. The anterior and inferior surfaces run into each other without a definite boundary line and form the posterior portion of the roof of the nasal fossa and the roof of the choana. The orifice of the sinus is situated in the upper part of its anterior wall, behind the superior turbinated body (Fig. 2). The outer wall is in relation to the optic nerve and internal carotid artery (Fig. 6). This wall is often very thin, and disease of the sphenoid sinus is often accompanied by optic neuritis. The sphenoidal septum is sometimes obliquely placed, so that one cavity lies in front of the other.

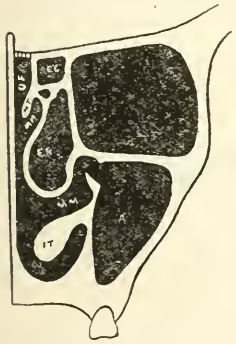

Fig. 9.—(Modified after Hajek.) EB. Enlarged ethmoidal bulla simulating middle turbinate. MT. Middle turbinate. AEC. Anterior ethmoidal cell. O. Orbit. A. Antrum. MM. Middle meatus. IT. Inferior turbinate. OF. Olfactory fissure.

We may divide the cases of accessory sinus suppuration, from the diagnostic viewpoint, into two classes, the closed and the open, *i.e.* those in which there is no pus to be seen in the nose, and those in which there is a purulent discharge to be seen in the nasal cavity.

The majority of the closed cases are acute. The cases of chronic empyema of the accessory sinuses, without discharge, are rare. Often a chronic case which has been discharging freely is transformed into an acute closed case, as a result of closure of its ostium from acute swelling of the mucous membrane. In the cases of acute closed empyema of one or more of the accessory sinuses, we have headache, more or less intense, with a feeling of fullness and obstruction in the nose. There are general febrile symptoms. There may be edema of the skin over the sinuses when the frontal or maxillary sinuses are involved. Sometimes, in the acute cases of closed frontal sinus disease, there is displacement of the eye downward and outward, due to edema or pus in the orbit. This is more likely to occur in those cases of ethmoidal suppuration in which there are dehiscences in the os planum. However, there may be protrusion of the eyeball without a perforatoin in the orbital wall of frontal or ethmoidal sinus. This condition may even exist without pus in any of the sinuses. In some of these cases we find only granulations and necrotic bone in the sinuses.

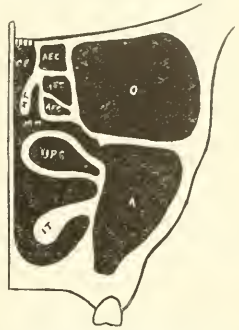

Fig 10.—UPC. Dilated cell in unciform process simulating middle turbinate. MT. Middle turbinate. IT. Inferior turbinate. MM. Middle meatus. OF. Olfactory fissure. AEC. Anterior ethmoidal cells. O. Orbit. A. Antrum.

Very often in cases of acute closed frontal sinus disease, the symptoms are referred entirely to the eye. This is well illustrated in the following case: A young fireman, about thirty years of age, thought that he had gotten a cinder in his left eye. He had had intense pain in his eye for several days. His family physician was unable to find anything in his eye and referred him to me. Except for a slight congestion of the conjunctiva, the eye looked normal. The pain seemed to me to be much more intense than anything that could be caused by a foreign body in the eye. Upon asking him whether he had any trouble with his nose he was most emphatic in his denial. The forehead over the region of the left frontal sinus was very tender to pressure. Upon intranasal examination there was discovered a boggy swelling of the left-middle turbinate, completely closing off the middle meatus, and several polpi. The polypi were removed along with the anterior end of the middle turbinate. There was a gush of pus with immediate relief of his pain. Sometimes the only symptom is a supra-orbital neuralgia. Occasionally it is an impairment of vision, which may go on to complete blindness. This is due to a retrobulbar optic neuritis, and occurs in cases of sphenoiditis and posterior ethmoiditis.

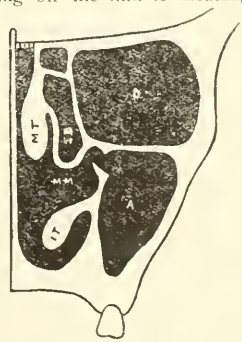

Fig. 11.—EB. Ethmoidal bulla. MT. Middle turbinate. IT. Inferior turbinate. MM. Middle meatus. O. Orbit. A. Antrum.

We see in Fig. 6 how close the optic nerve may lie to the outer wall of the sphenoidal sinus. In some cases there is a dehiscence in the bony wall, so that the nerve sheath lies in contact with the mucosa of the sinus. In those cases where the posterior ethmoidal cells extend backward over

the sphenoidal sinus the optic nerve is in direct relation to the ethmoidal cell, as is seen in Figs. 7 and 8.

Intranasal inspection does not usually show any very striking changes in the acute closed empyemas. We usually find some edema and enlargement of the middle turbinated body with obstruction of the middle meatus. In the chronic open cases which become transformed into the acute closed cases by sudden closure of the ostium we usually find irregular hypertrophies together with polypi in the region of the middle meatus.

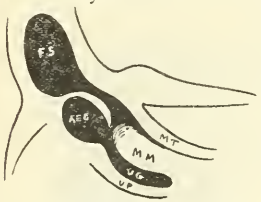

Fig. 12.—(Schematic after Sieur & Jacob.) FS. Frontal sinus opening into top of middle meatus. AEC. Anterior ethmoidal cell opening into unciform groove. UG. UP. Unciform process. MM. Middle meatus. MT. Stump of middle turbinate.

Transillumination gives us confirmatory evidence in disease of the frontal sinus and antrum, but tells nothing positive. The shadow varies with the size of the cavity and the thickness of the walls. Absence of the frontal sinus would give the same picture upon transillumination, as a badly diseased frontal sinus.

A much more valuable aid in diagnosis is the *x*-ray. Pus in an accessory sinus shows as a dis- which is a very valuable aid to us in our operative tinct shadow in the *x*-ray picture. In addition to showing the presence of disease the *x*-ray picture shows the size and outline of the sinuses, work. It is especially valuable to us in cases of frontal sinus disease. It shows whether the frontal sinus is present or absent, and how large it is; whether it is safe to enter the frontal sinus through its anterior wall, above the orbit, or whether the sinus is so small that it must be entered through its floor, in the roof of the orbit. It shows whether one sinus encroaches upon the other side of the forehead. It is very embarrassing for a surgeon, after he has passed a cannula into the frontal sinus and washed out pus, to make an opening through the forehead and find himself in a perfectly healthy sinus. Yet this is just what would happen in those cases where the septum is displaced very much to one side if we were not appraised of this fact by the *x*-ray picture. The *x*-ray picture also shows the presence of orbital recesses and frontal bullæ. Two pictures ought to be taken, one in full face, and the other in profile. In the former you can compare the diseased with the healthy side. This picture shows the lateral extent of the frontal sinus. The profile picture shows the depth of the frontal sinus, the presence of orbital recesses, the relations of the ethmoidal cells to the frontal sinus, and the presence of disease in the sphenoidal and ethmoidal cells.

Even this method does not always show the presence of pus. The only positive diagnostic method is the washing out of pus from the affected sinus. This is done either through the normal ostium or through the bony wall of the sinus. In the acute closed empyemas, it is usually impossible to introduce a cannula into the ostium of any of the sinuses, without removing the anterior end of the middle turbinated body. In order to get at the sphenoidal ostium it is usually necessary to remove the entire middle turbinate. Occasionally, we can succeed in entering the ostia without removing any turbinate tissue by shrinking down the mucous membrane of the middle meatus with cocaine and adrenalin.

As removal of the anterior end of the middle turbinate is usually a part of the treatment for disease of the accessory sinuses, I do not hesitate to resort to this procedure in order to reach the orifice of the sinus in all cases where there is a strong suspicion of empyema, when it is impossible to introduce a cannula otherwise. However, this procedure is unnecessary in the case of the antrum of Highmore as this cavity can easily be entered through the inferior meatus by means of a trocar.

The cases of chronic closed sinus disease are comparatively rare. In this class may be included the cases of so-called mucocele of the frontal sinus. This is not really a suppurative condition. As a result of obstruction in the nasofrontal duct there is an accumulation of mucous secretion in the frontal sinus which takes on a cystic character. There is a gradual thinning of the walls with dilatation of the cavity usually in the direction of the orbit, so that the eyeball is displaced downward and outward. Usually there are no other symptoms beside the deformity. There are usually no marked intranasal changes to be seen.

The open cases of empyema may be acute or chronic. In these cases we find pus in the nasal cavity, and it is very easy to make the diagnosis of empyema, but not always so easy to locate the affected cavity.

The acute cases of empyema are not often open at first. Later on, when drainage is reestablished, either naturally, by a shrinkage of the mucous membrane about the ostium, or through operative interference, they become transformed into the open type. The majority of the open cases are chronic. This class includes by far the largest number of cases that we are called upon to treat, as the acute cases often get well without ever having gone to see a doctor.

The principal symptom in the chronic open cases

Fig. 13.—Nasofrontal duct entirely surrounded by anterior ethmoidal cells. FS. Frontal sinus. AEC. Anterior ethmoidal cells. CUP. Cell in unciform process. UG. Unciform groove. FB. Frontal bulla, with probe R showing its ostium in middle meatus. A. Anterior ethmoidal cell into which frontal sinus opens. O. Probe passing through anterior ethmoidal cell to reach frontal sinus. M. is a profuse, more or less offensive, nasal discharge. However, in cases of sphenoidal and posterior ethmoidal disease the discharge may pass into the throat through the choanæ instead of out through the anterior nares. On postnasal examination in these cases the pus can be seen trickling over the

tops of the posterior ends of the superior and middle turbinates. In many of the cases of ethmoidal disease, instead of there being a profuse discharge, the pus dries in the nose and accumulates in the form of dried crusts, which decompose and give rise to a very foul odor. This class of cases forms

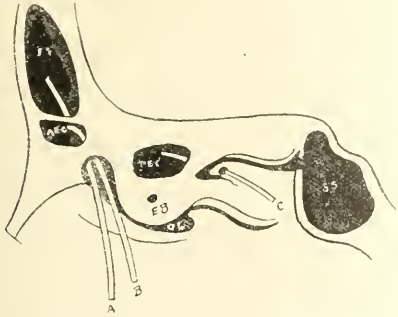

Fig. 14.—FS. Frontal sinus. AEC. Anterior ethmoidal cell lying to the inner side of nasofrontal duct. A. Probe entering frontal sinus. B. Probe entering anterior ethmoidal cell. UG. Unciform groove. one of the types of ozæna. It is possible to have a foul odor in disease of any of the accessory sinuses.

Next to discharge the most common symptom is headache. The headache is usually periodic and may be located in any part of the head. The location of the headache is no guide as to which sinus is affected. The amount of headache is in inverse proportion to the freedom of drainage. The more free the discharge, the less headache. Many cases have no headache whatever.

J. McC., fifty years of age, came to see me about a year ago for an acute infection in his left middle ear. Incidentally, he remarked that he had had a nasal catarrh in the left side for about forty years and asked me whether I wouldn't look at it. He said he had never had a headache or pain in his life, and the only thing that bothered him was the profuse discharge. There was an almost continuous dropping from his left nostril. Examination showed the left naris full of pus and polypi. After removing the polypi and a very much degenerated middle turbinate I was able to wash out a large quantity of foul-smelling pus from the frontal and sphenoidal cavities.

In some of the cases there is a subjective sense of bad odor. Where the middle turbinate is considerably enlarged there is complete loss of the sense of smell. There are often gastric symptoms from swallowing the pus at night. Sometimes the gastric symptoms are the only symptoms present. In cases of gastric disease that do not yield to ordinary methods of treatment it is always advisable to make a nasal examination in order to exclude accessory sinus disease.

On intranasal examination we usually find the changes much more marked in the chronic open empyemas than in the closed acute cases. In addition to the presence of pus, which is usually white and creamy, we usually find a hypertrophy of the middle turbinate, with irregular hypertrophies in the middle meatus, especially about the lips of the unciform groove. In a large number of cases, we find nasal polypi springing from the middle meatus.

In cases of atrophic rhinitis where the atrophy is confined to the inferior turbinate and the middle turbinate is hypertrophied, especially if the condition is unilateral, we usually have to deal with a case of accessory sinus disease.

In making a diagnosis of the chronic open empyemas, we use the same methods as in the acute closed cases, with the additional information that the location of the pus in the nose gives us. In examining a case of open empyema we should first clean the nose of all contained pus, and then place a pledget of cotton soaked in 5 per cent. cocaine into the middle meatus for a few minutes. Upon removing the pledget we should try to determine whether the pus is trickling out of the middle meatus or out of the olfactory fissure; that is, to the outer or the inner side of the middle turbinate. If the pus is coming out of the middle meatus one or more of the sinuses of the first series are affected, *i.e.* antrum, frontal, or anterior ethmoidal cells, as these drain into the middle meatus. If the olfactory fissure is the source of the pus, then we are dealing with disease of one or both of the sinuses of the second series, *i.e.* posterior ethmoidal or sphenoidal sinuses. We should also make a postnasal examination to see if there is any pus trickling on to the roof of the nasopharynx from the choana. If this is found we are dealing with disease of the sphenoid or posterior ethmoid cells.

Now, it is not always possible to tell whether the pus is coming from the middle meatus or olfactory fissure, because we cannot always tell whether the body that we are looking at in the situation of the middle turbinate is really the middle turbinate. We may be dealing with an enlarged ethmoidal bulla, which has crowded the middle turbinate up out of sight, as in Fig. 9, or with an hypertrophy of the unciform process, as in Fig. 10. In either of these cases pus coming out of the middle meatus would appear to be coming from the olfactory fissure. Sometimes we see what appears to be a double middle turbinate, one portion lying external to the other. In such a case, both the middle turbinate and the ethmoidal bulla are enlarged and lying adjacent to each other (Fig. 11).

Fig. 15.—(Schematic after Hajek.) MM. Middle meatus. A. Antrum. O. Orbit. MT. Middle turbinate. IT. Inferior turbinate. W. Outer wall of middle meatus, fused with floor of orbit.

We can only be certain of what we have to deal with if we remove the mass. In order to explore the cells of the first series we need only remove the anterior end of the middle turbinate. To explore the cells of the second series we must remove the entire middle turbinate. This is done by means of the cold wire snare and biting forceps.

The orifice of the frontal sinus is situated at the upper end of the unciform groove, that of the antrum at the lower end of the groove, while the anterior ethmoidal cells open into the middle of the groove or just above it (Fig. 2). Therefore, our guide in exploring these sinuses is the unciform process which forms the lower boundary of the

unciform groove, and stands out as a distinct ledge on the outer nasal wall a short distance above the insertion of the inferior turbinate body.

In order to wash out the frontal sinus we take a cannula of about the size and caliber of a thin Eustachian catheter, and curve the end to an angle of about 145°. This is introduced through the anterior naris with the end directed upward. It is passed above the unciform process so that the end of the cannula lies in the unciform groove. The hand is then depressed and the end of the cannula allowed to slip upward and forward along the unciform groove until it is felt to slip through the orifice into the frontal sinus. This manœuvre is only rarely successful when the middle turbinate is intact. When the anterior end of the middle turbinate has been removed we can usually succeed in entering the sinus. But in about 25 per cent. of the cases we cannot succeed even then for various reasons. It sometimes happens that an anterior ethmoidal cell opens into the upper end of the unciform groove and the frontal sinus opens behind and above this into the anterior extremity of the roof of the middle meatus as is shown in Fig. 12. In such a case, the cannula would be in the anterior ethmoidal cell when we would imagine it to be in the frontal sinus.

Fig. 16.—(Schematic after Hajek.) S. Anterior and inferior walls of sphenoid with ostium in upper part. MT. Middle turbinate. IT. Inferior turbinate. PEC. Posterior ethmoidal cells. O. Orbit. A. Antrum.

Sometimes the upper end of the unciform groove is entirely surrounded by anterior ethmoidal cells which open into the groove from all sides (Figs. 13 and 14). It is very easy for the cannula to slip into any of these cells. Sometimes the frontal sinus opens into an anterior ethmoidal cell, which in turn opens into the unciform groove, so that, in order to enter the frontal sinus, the cannula would have to pass through the anterior ethmoidal cell. Very often the cannula breaks through the thin walls of one or more of the ethmoidal cells before it enters the frontal sinus. Therefore, the results of washing out the frontal sinus are of diagnostic value only where the findings are positive. Where the washings return clear we cannot be sure that we have been in the frontal sinus unless we take an *x*-ray picture with the cannula in situ.

In order to enter the antrum, the cannula is introduced above the lower end of the unciform process, and turned directly outward. This is not a very easy procedure. For practical purposes it is much simpler to enter the antrum through the bony nasoantral wall with a trocar. This is an absolutely painless procedure, if the wall is cocainized by applying a pledget of cotton soaked in 5 per cent. cocaine for several minutes. We can perforate either through the middle or inferior meatus. The middle meatus is the thinnest part of the wall, being membranous in some parts. This is theoretically the ideal site for the puncture, but there is an element of danger. Occasionally the outer wall of the middle meatus bows out and fuses with the floor of the orbit, so that a trocar passing through this wall would enter the orbit instead of the antrum (Fig. 15). My custom is always to puncture through the inferior meatus. If the end of the trocar is turned upward and outward under the inferior turbinate, so that it passes through the upper part of the outer wall of the inferior meatus, just below the insertion of the inferior turbinate, it will always encounter fairly thin bone, through which it can pass without any difficulty. The lower part of the nasoantral wall is usually fairly thick. If the needle were passed through the lower part of the outer wall of the inferior meatus, it would usually encounter considerable resistance. In some cases the floor of the antrum does not reach as low a level as the floor of the nasal fossa, so that the antrum could not be reached at all through the lower part of the meatus.

If both the frontal sinus and antrum are found to be healthy, in a case in which pus is coming from the middle meatus, the disease must be confined to the anterior ethmoidal cells. Often two or all three of the sinuses are affected together. If the pus comes from the olfactory fissure or through the choana on to the roof of the nasopharynx, the disease is located in the sphenoidal or posterior ethmoidal cells.

In order to wash out the sphenoidal sinus, it is usually necessary to remove the entire middle turbinated body, except in well-marked cases of atrophic rhinitis. When this is done the anterior and inferior walls of the sinus are plainly seen 2½ to 3 inches from the anterior naris, with the ostium in the upper part of the anterior wall near the septum (Fig. 16). If the sphenoidal sinus is diseased, we can usually see the pus trickling out of the ostium. The cavity can be washed out through a straight cannula, or a cannula with the end slightly bent downward. If the sphenoidal sinus is healthy then the disease is located in the posterior ethmoidal cells.

Suppurative disease must be differentiated from tumors and cysts of these cavities. Benign tumors of the accessory sinuses are rare. Malignant tumors are somewhat more common. The types of tumors most commonly found are sarcoma, carcinoma, and endothelioma. The antrum is most often involved. These cases are differentiated from the cases of suppurative disease by the deformity, displacement of the eye, and occlusion of the nares. If a trocar is introduced through the inferior meatus it meets a resisting body in the cavity of the antrum. Usually the washings return clear or blood-tinged, although it is not so very uncommon to have pus in an antrum which is the seat of a malignant tumor. The tumor may perforate through the nasoantral wall and project into the naris, where a piece may be removed and examined microscopically.

In a case presented by Dr. Voislawsky and the writer, at a meeting of the laryngological section of the New York Academy of Medicine, in November, 1909, the diagnosis presented numerous difficulties. This was a case of epithelioma of the antrum complicated by suppurative disease of the frontal and ethmoidal sinuses, with marked exophthalmos. The *x*-ray picture showed disease in all the sinuses on one side. Pus could be washed out of the frontal sinus with a cannula. The washings from the antrum were clear. The diagnosis was based on the absence of pus in an antrum which showed a decided shadow in the *x*-ray picture. The exophthalmos was no guide in this case, because it might just as well have been due to the disease in the frontal sinus, as to the condition in the antrum.

The most common form of cysts of the accessory cavities are the dentigerous cysts of the antrum of Highmore. These cysts, especially when they reach a large size, are often mistaken for empyema. The diagnosis is usually not made before operation. If the antrum is washed out through the normal ostium, the washings return clear, because the cyst is closed off from the cavity of the antrum.

My excuse for reading a paper of this sort before a general society, is that it gives me an opportunity of reminding you that accessory sinus disease is a very common condition, and many of these patients come to see the general practitioner, without suspecting that there is any nasal condition. Often they only complain of headache or gastric disturbance. Accessory sinus disease should always be thought of in cases of persistent headache. Every doctor can recognize the gross intranasal changes in these conditions, such as polypi and pus. In every case of headache from grippe one should determine if there is any tenderness over the frontal sinus or antrum. If this is followed out as a routine procedure, one will be surprised to find how many cases of acute sinusitis will be brought to light.

156 East Sixty-first Street.

DRAINAGE AND DRESSING OF WOUNDS IN MINOR SURGERY.*

By ARCHIBALD E. ISAACS, M.D.,

NEW YORK.

SURGEON, BETH ISRAEL HOSPITAL.

When I was honored with an invitation to address this Society and the suggestion was made that I speak on some surgical subject of interest to the general practitioner, I decided on drainage and dressing of wounds in minor surgery, that is of wounds as they come to the general practitioner in his everyday work, as a suitable topic that would be of interest. In these remarks I will not attempt to cover the entire subject, but merely to speak of certain features which appeal to me as worthy of discussion. My observation has been that the underlying principles are frequently overlooked, or possibly not understood, and, therefore, the methods used are not adapted to bring about the results desired. Judging from what I have seen in a long experience, it seems that there is an idea widely prevalent that the treatment of wounds is to pack them as full of gauze as possible. It looks as if a supposed unwritten rule, "When you see a wound, pack it full of gauze," were followed by a large proportion of practitioners. No sense of reason seems to be exhibited and physical and physiological principles are ignored or forgotten. In place of treating wounds by rule or routine, each case should be considered as to its own peculiarities and necessities, and treated accordingly.

To understand the subject and appreciate the reasons for the use of various measures, let us begin with the fundamental principles and consider in the first place, why is drainage needed? What reasons call for packing? And what are the objects of the application of dressings?

Nature's means of ridding the system of objectionable and injurious material is the production of a circumscribed inflammation and exudation of leucocytes with the formation of pus which, when confined, constitutes an abscess. Nature's further process of disposing of these exudates is by furnishing drainage through an opening produced by what is popularly called pointing and breaking of an abscess, or the surgeon's knife anticipates this outcome by furnishing an incision. This opening is the natural drainage channel and, unaided, serves its purpose just so efficiently as the natural conditions permit. But there are various reasons why the opening in itself may not prove sufficient and why artificial assistance may be advantageously employed. The main reasons are the tendency of the opening to close before suppuration has cleared the parts of infection and put them in condition to heal. This closure may be either by adhesion of the raw edges of the wound, or by contraction of the newly formed granulation tissue in wounds of longer standing. In most cases this tendency has to be combated through artificial drainage. Drainage, therefore, is assistance given in providing and retaining an unobstructed outlet for exudate that if not gotten rid of would stagnate or collect under tension.

Packing a wound or cavity is called for under certain conditions; a frequent instance is for control of hemorrhage after incision. Another instance is in the after treatment of certain wounds, after incision for fistula in ano, for instance, where it is necessary to keep the wound edges apart during granulation to prevent their union before thorough healing of the base of the wound. There are certain wounds that may require a packing, if it may be called such, for drainage purposes. An example would be suppurating cavities with comparatively large openings and with rigid walls, which do not allow the cavity to collapse, and are so situated that the accumulating exudate would gravitate into them and have no outlet except by running over. Bone cavities would act in this way, or chronic abscesses whose walls had become thickened and hard as the result of long-standing inflammation. These cavities may be filled loosely with gauze, which displaces the pus, and at the same time soaks it up and carries it into the dressings. When packing is used for the control of hemorrhage or for keeping the sides of the wound from coming in contact, as in the first two instances mentioned, its object is not drainage, and it may be, and in fact, should be, packed as tightly as needed. But in the last instance, when it is intended merely to fill up the space of a patulous cavity, it is important to remember that drainage is also an object and it must, therefore, be placed loosely enough to allow it to soak up and carry away the purulent discharge.

Dressings are applied to suppurative wounds with two main objects: Firstly, to protect the wound from external influences especially from new infection, and secondly, to provide means for the absorption and removal of the exudate from the wound.

Bearing these first principles in mind, we will return to the discussion of drainage. I have laid stress on the recognition of Nature's mode of securing drainage to make it evident that whatever artificial methods are used should be on the lines of assistance of Nature's efforts. This applies not only to this particular subject, for the whole science of medicine is based on the observation and study of the natural processes, and their adaptation or direction along certain lines constitutes the various methods of treatment. Whatever we do, therefore, must be based on Nature's methods because we can

*Read at a meeting of the Williamsburg Medical Society, April 11, 1910.

not change them; all we can do is to interfere with them to a certain extent and such interference may be for good or for harm, and, in instituting such, let us as least endeavor to avoid doing harm. There are many occasions where wounds would do better if not drained or packed at all. If the external wound is a comparatively large one and open, with no tendency to premature adhesion or to retention of discharges, there is no need for drainage, and unless there be some special reason to keep it open, as in cases already referred to, there is no need for packing. Where there are no reasons for drainage or for packing it is better not to use either, for under such conditions they retard healing, and act as foreign bodies, increasing inflammation and suppuration, besides causing needless pain in their application.

The material most generally used for drainage is gauze. This will drain under certain conditions and not under certain others, and on many occasions even when it does drain there are other means that would do it better. Where gauze is serviceable is in large open wounds where the extent of the cavity is not much greater than that of its external opening and where there is a free discharge. Here it will drain, or rather, it will not interfere with drainage, as the copious secretion will keep it moist and pervious and the opening is too large to crust over by drying of the secretions. But under these conditions artificial drainage is hardly necessary. The gauze here rather serves to fill a patulous cavity, and hold its walls asunder, which would be of advantage in the treatment of an infiltrated region shortly after incision and before the tissues have drained out sufficiently to permit the parts to heal. Or, as mentioned previously, the gauze might serve to fill up the space of an open cavity, and thus displace the pus that would otherwise gravitate into it.

But there are wounds that will not drain satisfactorily without assistance and where measures for the establishment of efficient drainage are necessary. This is especially the case where the suppurating cavity is large in proportion to its opening. If a strip of gauze is packed into such an opening what happens? The gauze makes a good beginning at drainage by soaking up an amount of the exudate and, by its capillarity, carrying it outside the wound to be absorbed by the dressings; but this exudate is a viscid liquid and does not follow fast enough to overcome the drying effects of the evaporation which takes place, and which takes off only the water and leaves the mesh of the gauze permeated with, and obstructed by, the solid residue. With its mesh obstructed, the gauze cannot drain any further, as its capillarity is destroyed. Besides this the gauze, especially in a fresh wound, has a way of adhering to the surrounding raw surface and, with the drying of the secretions in and about it, is transformed into a hard impermeable plug securely glued to the skin about the wound and firmly closing up the opening. This is the result and is just the opposite of that desired. In place of providing means of egress for the accumulating fluid it stops up the opening as securely as could possibly be done if the object sought were to seal it, almost as if it were corked up with a plug of gauze dipped in glue. I have seen this sort of dressing many times, a felon, for instance, with a homeopathic incision, and that plugged up literally, as described, and with a collection of pus backed up under tension behind the drain, causing severe pain. Small scalp wounds are also prone to act in this way when infected, the suppurative process spreading under the fascia in all directions from the wound which is sealed up with the bit of gauze which was intended to drain it. Lymphatic abscesses of the neck, axilla, or groin, with small openings, are other instances that frequently come to the surgeon with these conditions. In all of these cases there is no drainage and, consequently, no relief to the pain or other symptoms, and no stop to the spread of the suppurative process. The unfavorable results are especially pronounced if dry dressings are superimposed on this sort of drain; they are not so marked when wet dressings are used because the moisture of the dressing prevents the drying of the secretions on the gauze drain. Yet the character of the purulent discharge, containing, as it does, considerable particles in suspension, is such that the mesh of the gauze becomes clogged and its capillarity destroyed, and while under these conditions it is not as bad as when allowed to dry, it is not as satisfactory as a drain ought or could be. If water were the fluid to be drained gauze would be a satisfactory medium, but under conditions mentioned and for reasons stated it is not satisfactory when the material is a viscid mixture like pus.

When gauze does drain under these conditions it is not because of its capillarity, though that may contribute in inconsiderable amount towards the result. It drains in the same manner as the non-capillary material used for drainage to be spoken of presently, that is by permitting the discharges to exude between its circumference and the drainage tract surface. It cannot act this way in a fresh wound where the gauze becomes adherent to the wound surface; but in a wound or sinus arrived at that stage where its surface is covered with granulation tissue, the gauze does not adhere and it may, therefore, drain in the manner mentioned.

The essential need for drainage is an unobstructed outlet, for, in most wounds, what carries the fluids out is the internal pressure of the tissues, a *vis a tergo*, that forces them out. They are not drawn out by any applications, even by drains except in a comparatively insignificant amount when capillary drains are used. The favorable effects that any applications or drains may have are due to their establishing conditions more favorable to the exit of the fluids, actuated by the internal pressure of the tissues. Conveyance by a *vis a fronte* through capillarity of the drain would be of advantage if it could be secured, but practically except under conditions already referred to, this can not be attained.

Capillarity, upon which the claims of gauze as a drain are based, is, as we have seen, not an essential but is necessary when gauze is used, because this material fills the lumen of the outlet as a cork does the mouth of a bottle, and in fresh wounds adheres to the raw edges. Thus it affords no other outlet to the secretions than that through the capillary spaces of its mesh.

That tubes of rubber or glass drain better than gauze is not due, as popularly supposed, to their draining through their lumen. They do not drain so, at least in the majority of cases, though there may be a minority where the exudate is watery and where conditions favor tube drainage. The lumen in most cases becomes clogged with sloughs or necrotic tissue or the granulation tissue from the wound surface grows into it through its open end, or side openings if it have them, and completely

clogs it up, as observation of a tube *in situ* for any length of time will show.

The reason that tubes drain better than gauze is that they do not become adherent to the raw surfaces as gauze does, and, therefore, allow exit of fluids between their circumference and the wound edges. For the same reason, what is usually called a cigarette drain, that is, a core of gauze with rubber tissue wrapped about it, drains better than gauze would by itself, and has the advantage that it does not become adherent to the raw surfaces. This is of special importance in abdominal drainage, as bare gauze, besides the fact that it does not drain, becomes adherent to the serous surface of the viscera, and is liable to do considerable damage on its withdrawal. The irritation of its presence also sets up an inflammation which is likely to result in troublesome postoperative adhesions. The so-called cigarette drain also has the advantage over tubes of rubber or glass, that it is soft and flexible and not so liable to cause pressure necrosis of the tissues on which it lies for days and sometimes for weeks. In abdominal drainage, especially, is this important, as serious harm is often unnecessarily done by pressure of tubes on the delicate viscera.

In the combination of rubber tissue wrapped about a core of gauze, this so-called cigarette drain, the gauze plays an insignificant part, practically not to be considered, in the drainage process. The great bulk of the discharge finds its way out around the circumference of the drain, and the amount that soaks through the gauze is comparatively so small that it deserves no special consideration. That this is not generally appreciated is evident from the fact that many surgeons construct their cigarette drains with a tuft of gauze protruding from the inner end and with a series of openings cut in the tissue along its course, exposing the gauze for the purpose of giving it more opportunity to soak up and carry away the fluids. But as the gauze does not do this to any appreciable extent there is nothing gained by it, and there is the disadvantage, especially in intraperitoneal work, that the exposed gauze becomes adherent to the raw surfaces with the unfavorable possibilities previously mentioned.

The maintenance of an unobstructed outlet is necessary until the cavity below is in condition for healing to take place over it, and this outlet must be kept from closing by adhesion or pasting of the edges of the wound or by cicatricial contraction of the drainage tract. The means used to carry out these indications must at the same time not obstruct the free outflow of the secretions. Gauze, as we have seen, while it has its uses and advantages in certain cases, does not answer requirements in many others, especially where the drainage tract is long and narrow, or where the opening is small in comparison with the cavity to be drained. Under these circumstances something that will meet these indications must be found to replace it.

Where, as in the majority of instances, simply drainage and not packing is required, gutta percha tissue is the ideal material for the purpose. In a single thickness it is too frail for practical use, but it may be folded into a strip of a suitable number of layers, from four to twelve, according to requirements. The length of the strip should be taken with the grain of the tissue, along which it readily tears. If taken across the grain there is the possibility of the strip tearing transversely on introduction or removal, and the possible unobserved loss of a piece in the wound. In cases where a more bulky drain is desirable, or where it is necessary to maintain some distention of the sinus or superficial opening, the tissue may be wrapped around a core of gauze to give it body.

Guttapercha tissue serves to keep the wound open as any other drain does, but gives more assurance of satisfactory drainage because it does not adhere to the wound surfaces, and does not permit of the discharges drying on it about the outlet and so pasting up the opening. Besides that, it is not so irritating as gauze and its smooth surface permits it, on introduction or removal, to slide along on the raw and sensitive tissues with much more ease of application and with much less pain to the patient than gauze, which catches on the raw surfaces and has to be forced in or out.

The absorptive qualities of the outer dressing are very important in relation to the efficiency of the drain. The discharge, as it exudes from the wound, should be taken up by the dressings so that it does not collect at the opening and dam up the drain. Here again there is seldom any difficulty when the discharge is sufficient in amount to keep the dressings moist, but if the amount be scanty, the small quantity will permeate the gauze directly over the wound and dry in its meshes forming a hard, crusty shield impervious to the discharge that follows. To obviate this the absorptive properties of the gauze must be assured, not only by applying it moist, but by keeping it moist. A wet dressing that will stay wet not only assures absorption, but is comfortable and gratifying to the patient.

As to the choice of an antiseptic solution with which to moisten the dressing, a 1 to 4,000 bichloride is most satisfactory generally, but at times sets up a dermatitis; boric acid solution and liq. alumni acetatis are the mildest and least irritating, and there are very few cases that will not tolerate their continued use. As to carbolic acid, I want to be as emphatic as possible in warning against its use, no matter in how mild a solution, on fingers or toes. Too many have been sacrificed in this way, though generally this fault is found to lie with the patient who uses it on his own initiative or with the counter prescribing pharmacist; physicians' orders are responsible for a few and these few are just that number too many to the discredit of the profession.

One more word, and an important one, in regard to wet dressings, and that is that to be efficient they must not only be applied wet, but must be kept so. There are two ways of doing this. One is by applications of additional solution at intervals; the other by preventing evaporation from the dressing as applied, by covering it with some impervious material, usually guttapercha tissue. In making use of the repeated applications of additional solution, care must be taken, especially if the dressing be a bulky one, that sufficient solution be used to penetrate the dressing before it has a chance to evaporate from the outer layers. When used on the extremeties, an excellent method is to have the part, with the dressings undisturbed, inserted into a basin of solution; hand or foot baths may thus be made as often as necessary to keep the dressing wet. These baths are also grateful to the patient and have the additional advantage, in freely suppurating cases, that they wash away the excess of discharge and with it the odor and dirtiness of its accummulation from one dressing to the next. An objection to this variety of wet dressings is that they wet and soil anything with which they come in contact, and they are, therefore, inconvenient for patients at-

tending to their usual occupations. Even with bedridden patients the bed becomes soiled if not protected with a rubber sheet or some such device.

Envelopment of the dressing in guttapercha tissue permits of the outer bandage being dry, while the inner dressing may be as wet as desired; but to serve its purpose the tissue must be properly applied. There is a right way and a wrong way of using it. My observation has been that the wrong way is that generally used, which furnishes another instance of things done by rote or rule without regard to, or possibly without knowledge of, the purpose of the procedure. It seems to be the idea that if a piece of tissue is applied over a moist dressing, it fills the requirements irrespective of whether it is placed to properly cover in the dressing or not. In many instances it seems that not only is no thought given to the reasons for, or purpose of the application, but no lesson seems to be learned from the observation of its inefficiency which should hardly escape notice when a dressing that should be wet is found dried out under the rubber tissue and pasted to and clogging up the drainage openings. For the dressing to hold its moisture, it is essential that it be thoroughly covered in with the tissue, for if the smallest portion be left exposed, the outer dressings absorb the moisture through this defect, and evaporate it not only from the vicinity of the defect, but gradually soak it up from the entire dressing. The result is that, though it may take a little longer, the dressing dries just as surely as if no tissue were used. To preserve its moisture the dressing must not only be thoroughly covered, but the tissue should extend beyond it on all sides, so as to come in liberal contact with the bare skin all around.

The use of guttapercha tissue in the treatment of burns or other superficial excoriations is not new, but it is not sufficiently in use. Gauze applied directly to a burned surface sticks to it even if applied moist or with salve, and any motion of the part puts a strain on this attachment with consequent continuous irritation or pain. Worse than this is the change of dressings when the gauze has to be torn from its attachment to the sensitive surface causing not only severe pain but traumatism to the wound and often with free bleeding from the granulations. All this can be obviated by the application of guttapercha tissue directly to the wound surface. The same qualities that make the tissue so satisfactory as a drain apply here in making it not only a most efficient application for healing purposes, but the one that will afford the most comfort as well. Its smooth surface is not irritating to the sensitive wound and its flexibility allows it to adapt itself closely to the surface and act as a protection against outside irritation. To permit drainage of the wound discharges it should be applied in strips of one-quarter to one-half inch in width, laid parallel to one another, with minute spaces intervening, just sufficient for the discharges to ooze through. Over this a wet gauze dressing, to assure absorption of these discharges, should be applied and this in turn covered with a sheet of the tissue to preserve its moisture.

Salves or dusting powders may be used directly on the wound, under the tissue strips, if desired for their mental or supposed beneficial effects, but the wounds do just as well, and in most instances, better, without them.

In the daily pursuit of our professional work we accomplish many things that give us inward satisfaction that we have done well. In the majority of instances these accomplishments are such that only we ourselves can appreciate; the layman or patient can not share our satisfaction, for he is not in a position to understand our work. These agreeable experiences serve us in helping to neutralize the ill effects of the unpleasant incidents that must also come our way, and they make life and the practice of medicine more pleasant and agreeable. But these mental effects do not help us in a material way, and material results are necessary to get along. Appreciation of our work by the patient is necessary for material assistance, and when we can obtain that in addition to our own personal satisfaction we have accomplished a double purpose. Relief from pain is one of the things a patient will be most grateful for, and in the dressing of wounds there are many opportunities to afford this. A simple change in the manner of dressing will often accomplish it and it will be evident, even to the patient, that this was the means of relieving his pain. Substitute a slip of guttapercha tissue for a plug of gauze in the small opening of an abscess and apply a wet dressing over it in place of the dry one that probably had to be soaked loose before it could be removed from its fastenings about the wound, and you have accomplished something that the patient will appreciate and which, at the same time, may afford you the satisfaction of knowing that, besides the relief of pain, you have put that wound in a position to heal and probably have averted serious complications that often result from faulty or obstructed drainage.

1325 Madison Avenue.

FISTULA IN ANO: EXCISION AND SUTURE.

By DR. E. C. BECK,

NEW YORK.

ATTENDING SURGEON TO ST. MARK'S HOSPITAL, INSTRUCTOR OF SURGERY AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL AND HOSPITAL, ETC.

It has always seemed rather unnatural to me to watch the long-drawnout process of healing following the usual method of operation for fistula-in-ano. The wound, which is made by the operator, is in the most unclean locality of the human anatomy, and no matter how sincere the patient may be in his efforts at following the instructions of his medical adviser, there is always the possibility, nay, probability, of infection and interference with quick healing. And that is one thing the patient, especially the business man, wants. Most of these cases occur in persons of sedentary habits or occupations. It was most of all this thought of getting these patients well in the shortest time that urged me on to try a procedure which has proved to be highly efficient, and most satisfactory to the patient.

The name fistula in ano has been used time out of mind to cover a multitude of sins. All sorts and kinds of openings within a short radius of the anus have been so called. "A rose by any other name may smell as sweet," but call a spade a spade. A true fistula in ano to my mind means a communication between the lower end of the bowel and the outer air by an auxiliary and unnatural opening. The anatomists describe a complete and incomplete form. The incomplete has either a blind internal or external extremity. The names easily explain the condition. The principal cause is probably an existing lax condition of the mucous membrane of the gut and often an existing anal or ischiorectal

abscess. It is the ischiorectal abscess that usually causes the incomplete form with a fistula opening externally.

In cases of blind internal fistula the sinus may be felt by digital exploration, and on insertion of a speculum can be seen and a probe inserted into it. Force the probe through the tissues externally and make a complete fistula of it. The same should be done with the blind external variety, so that in the end we shall always operate upon a case of complete fistula. Of course the blind external fistula may simply be a sinus resulting from an ischiorectal abscess. The introduction of the probe will verify the diagnosis and if found advisable on the part of the operator, may simply be curetted and drained.

If a fistula has been existant for some time and we split it open we find that scar tissue has formed and a well-defined channel has been built up. It appeared to me, therefore, that this tube was simply a means to an end and not the exciting medium. Results have confirmed this contention. The method is a simple one, and I am convinced that many have utilized it before me, but were too busy to publish it. I may add that we have given E. Beck's bismuth paste a thorough trial, but failed utterly with it.

The patient is admitted to the hospital on the day before operation and is well purged. He is allowed no solid food whatever, and his colon is thoroughly evacuated by enema one hour before operation. Anesthesia is usually by ethyl chloride, as the operation is a short one, and the patient later on is the better for it. A probe is inserted into the canal and pushed through until it can be felt by the finger in the rectum. A grooved director is now slipped in over the probe. I use it because it is a more powerful instrument and will not bend when traction is exerted with it. Running the tip of the scalpel along the groove the tissues are slit open with one sweep. Be sure to cut through the sphincter at right angles and it will reunite perfectly. Have the wound surfaces spread well apart and carefully remove all scar tissue in view with a sharp, blunt-pointed scissors. If in doubt rather cut away a little too much than not enough. Pay particular attention to the internal end of the wound. When all the offending tissue has been removed paint the whole surface over with tincture of iodine. I am firmly convinced that the highly antiseptic properties of the iodine are the dominating factor toward union by first intention. The scanty bleeding can easily be controlled by sponging.

Great care must be exercised in bringing the severed tissues together closely and accurately. For suturing material I use silk-worm gut and find it excellent for this purpose. The first suture is placed at the inner angle of the wound. The edges of the gut and sphincter are brought together with mouse-toothed forceps and a generous bite taken with the needle. A strong needle is imperative. Be sure you get enough tissue with your suture, as it will form a cushion when you exert pressure and will tend to keep the wound surfaces closely approximated. Sometimes it is necessary to make the suture for the sphincter an extra one, especially in those cases in which the fistula opens fairly high up in the gut. Leave the ends of the suture long, clamp it, and let them hang down out of your way. Sew up the rest of the wound in like manner, placing a stitch about every half inch and burying your needle deeply each time. Leave all the ends long, and when you have finished carry them all to one side and fasten them to the buttock with adhesive plaster. This will prevent irritation of the parts and add to the comfort of the patient. When the operation is completed a T binder is applied.

The patient is kept on his back and in bed, and his peristalsis held in check for at least four days by the administration of bismuth and opium. Only such nourishment is given as will leave the least amount of residue. When the patient begins to complain of cramps and colic his bowels are evacuated by means of an oil enema. He is usually allowed to go home at the end of the seventh day. At the end of ten days I remove all sutures excepting the innermost one, which should remain for two weeks to insure a perfect result.

Since the fall of 1908 I have operated upon 17 cases in this manner and have had only one in which the patient was not discharged as fully cured within two weeks. In that case I employed a curette instead of the scissors for removing the scar tissue and a stitch abscess formed at the outer angle of the wound.

A PITH-BALL MANOMETER.

By NATHANIEL FEDDE,

NEW YORK,

STUDENT, CORNELL MEDICAL COLLEGE.

The chief difficulty in taking blood pressure in the past has been in locating the point of minimum diastolic pressure. Determining which is the last of the oscillations of the mercury column is a decidedly unsatisfactory method. Ample evidence of this is furnished by the toleration offered bulky and complicated instruments like the Gibson and Erlanger, whose bulk is mainly for the purpose of simplifying this one point. Everyone recognizes that these instruments have an undisputed place in the laboratories because of their graphic features, but the practitioner who must carry them to the bedside and perhaps to six others where they are not needed before returning to his office refuses to be bothered with more weight than is convenient.

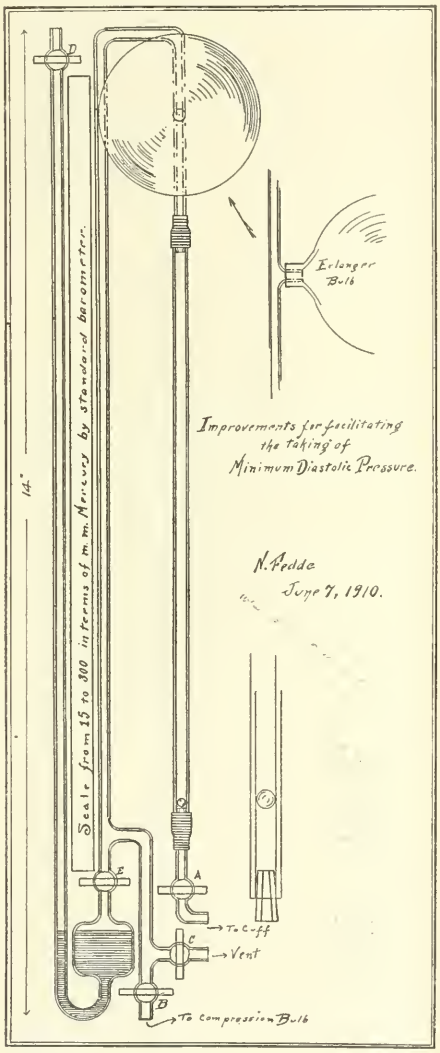
For these reasons I venture to place before the profession an idea that has been tried out by Dr. Sheldon and myself at the Cornell clinic, and found satisfactory. The instrument is portable, compact, and should, if properly made and boxed, not measure over 4 by 4 by 15 inches.

General Principle.—If with each pulse wave a fair volume of air be driven past a light freely moving object that object will move exactly as the mercury in the manometer, but with an exaggerated displacement. To accomplish this I let the air, which comes from the cuff, as a result of the increased pressure there, go past a pith-ball in a glass tube. The ball must be small enough to move readily, but not so small as to allow a too free passage of air. After passing the ball the air goes to an elastic rubber bulb, where it is compressed and the bulb itself expanded by each momentary increase in pressure caused by the pulse wave. In this way more air goes by the pith-ball than would be the case if the system were rigid and contained no more air than the tubing could hold.

Results.—The motion of the ball is, as near as the eye can tell, the exact duplicate of the tracing given by the Erlanger lever when a continuous record is taken during slow discharge of air. The excursions of the ball are larger or smaller than those of a well-balanced lever, depending entirely

on the weight of the ball and how well it fits the tube.

Technique.—Valves *A*, *B*, *D*, and *E* are opened and *C* is closed. (See Fig.) The compression bulb is worked until a point of pressure above the maximum systolic is reached (disappearance of pulse). Valve *B* is then closed and *C* turned so as to allow a steady, slow exhaust, the pressure falling about 1 mm per beat. Slight bounding movements of



the ball give warning when the pulse is about to return. These movements increase rapidly in magnitude, then remain about uniform until the minimum diastolic pressure is reached, when there is a marked diminution in the excursion.

The "Why" of Some of the Details Given in the Drawing.—The exhaust valve *C* is placed between the ball and the mercury so that every particle of air that leaves the cuff must pass the ball. The inlet tube is in the same place so that the pumping process may merely press the ball against the lower buffer rather than maul it against the upper. The two extremities of the manometer have stop-cocks *D* and *E* to prevent loss of mercury in transportation. This feature was seen on the Faught instrument. The tube containing the ball has a short piece of tubing of smaller caliber fused into each end to serve as a buffer. The lower buffer must be grooved so that the pith-ball cannot close the passage to cuff in ball-valve fashion. The mercury reservoir is introduced for two reasons. It brings the *T* for the inlet and vent near the operator's hand, and allows of greater space between each millimeter mark, thus facilitating reading, but requires that the tube be standardized. The tube containing the uith-ball is replaceable.

Summary.—The essential features of this instrument are compactness, portability, small expense of construction, and ease of reading combined with a reliable means of determining minimum diastolic pressure depending on large oscillations of a light pith-ball instead of minute oscillations of an inert column of mercury.

I wish, in conclusion, to express my appreciation of the encouragement and kindly criticism offered by Dr. Sheldon, Prof. Lusk, and Prof. Thompson.

Rectal Myomata.—F. Descoeudres describes a unique case of fibromyoma of the rectum. These growths are rare, only about 80 cases of intestinal fibromata being published, of which 16 involved the rectum. When internal they are polypi with pedicles of varying length. When external they develop upward into the abdomen, or downward and backward into the pelvis. The author's case developed backward under the skin of the region of the buttocks, and was so large that it hung down in walking and the patient sat upon it without any pain. It had a large fibrous pedicle attached to the upper wall of the rectum. These growths develop at the expense of the muscular coat of the intestine. They may be of congenital origin, a development of embryonic tissue, the immediate cause of the growth being irritation. They cause constipation, pressure symptoms, hemorrhage, and edema of the legs. The prognosis is bad aside from removal, since they endanger life by hemorrhage, obstruction of the bowels, or malignant degeneration.—*Revue de Gynécologie et de Chirurgie Abdominale.*

Some Considerations on the Treatment of Tuberculosis in Children.—P. Nobecourt says that fresh air, repose, and good hygiene are the important elements in the treatment of tuberculosis in children. Rest must be absolute whenever there is fever, emaciation, or joint tuberculosis. In others rest may be taken several times a day, interspersed with walks, but all violent exercise must be forbidden. As to fresh air, it cannot be attained in the city, but any climate may be suitable, it being advisable in many cases not to separate the child from its relatives, but to have a sort of home sanatorium in the country. Sea air is especially valuable in joint tuberculosis, in peritonitis, and in glandular cases. Early pulmonary cases, when the bronchial glands are involved, are especially suited to the seashore; in general afebrile cases do well there. The climatic treatment must go on for months in order to establish a cure. Cold sea baths are contraindicated under three years of age and in pulmonary cases. Warm baths may be given in all cases.—*Journal de Médecine de Paris.*

Chronic Ureteropyelitis in Pregnancy and the Puerperium.—O. T. Thomas says that (1) chronic infection of the urinary tract may, during gestation and the puerperium, by rapid proliferation of retained bacteria and the absorption of toxins, lead one to suspect infection of the parturient canal. (2) These infections may be of many years' duration, they may cause, from time to time, disturbances ascribed to the organs of generation. (3) Ordinary chemical and microscopical examination of the urine is not to be depended upon in these cases. (4) The diagnosis is easily made clinically, and readily confirmed by bacteriological examination of the urine.—*Cleveland Medical Journal.*

New York, July 16, 1910.

RESPONSIBILITY OF ARMY MEDICAL OFFICERS FOR THE SANITATION AND HEALTH OF TROOPS.

MAJOR EDWARD L. MUNSON of the United States Army Medical Corps has dealt with the above question in the Seaman Prize Essay for 1909. The points discussed in the essay are, as to whether army medical officers should be held directly responsible, and the limits of such responsibility. Responsibility is defined by the writer as absolute responsibility.

In the first instance, Munson points out that the duties of a civil medical officer and those of an army medical officer differ somewhat widely. The civil medical officer is entrusted, to the best of his ability, with the safeguarding of the health of a community. His is no divided duty. On the other hand the duty of an army medical officer is divided. In time of peace, his services approach somewhat closely to those of his brother in civil life, except that he is always subject to the commands of his superior officers, and indeed his work is ever subordinated to the good of the army; his real object is economic, to maintain military efficiency, and any other consideration is secondary. Of course, in time of war, medical officers must acquiesce in the disregard for health laws by a commander if actual military necessity so demands. From a perusal of the army regulations it will be gathered that the activities of medical officers with troops in posts or in the field are in a sanitary way officially limited to the functions of investigation, report, and recommendation.

It would seem to be proven with sufficient clearness that a medical officer cannot be held responsible for the health and sanitation of the troops with which he is serving, but that such responsibility is reposed in the commanding officer. This, thinks Munson, is as it should be, and the fault lies not so much in the army sanitary system as in the individual neglect and inefficiency of the officers responsible for its application; and the remedy lies in the creation of a strong central authority keenly alive to the practical military importance of sanitary results—an authority which would at least as quickly cause the court-martial of a commanding officer for maladministration of sanitary affairs as for maladministration in respect of property matters or the nonmaintenance of discipline.

Although Munson is of the opinion that medical officers should not be held directly responsible for the sanitation and health of troops, he yet believes that they should have a measure of power and responsibility. He holds the view that, first, a class of line officers should be developed and educated fully appreciative of sanitation and its results; second, the medical officer should be endowed not with direct responsibility for sanitary results but with executive authority within certain limits delegated to him by the commanding officer for whom he acts as an official but subordinate agent in the management of sanitary affairs. It is pointed out that the importance of good sanitation in an army is freely recognized by officers and that the type of officer who regards sanitary investigation as meddlesome and sanitary recommendations as more or less insubordinate criticism of his administration is fast dying out. According to Munson, then, what is needed to render the work of the army medical officer more effective, in addition to the suggestions quoted above, is that commanding officers should interest themselves personally in matters of sanitary administration equally with other administrative affairs, and that they should consider the surgeon primarily in the light of his military status as a staff officer, whose special technical knowledge, like that of the quartermaster, engineer, or commissary, should largely be drawn upon and used from time to time.

Undoubtedly the main *raison d'être* of the army medical officer is not that of a practising physician or surgeon, but is that of a preventor of disease. By neglect of proper sanitary precautions armies have been decimated by preventable disease. If the Japanese and German army authorities can prevent disease from gaining a foothold among the troops why cannot the American and British army authorities? The truth is that a more intelligent system is in vogue in the Japanese and German armies, and what is more to the point this system is rigidly carried out. Cooperation between the line officers and the medical officers as suggested by Munson would be a long step in the right direction, but unless the necessary sanitary measures are enforced by strict discipline these would be of limited effect.

THE RELATIONSHIP BETWEEN THE THYROID AND THE PARATHYROIDS.

THE importance of the parathyroids is now generally recognized, not only by physiologists and pathologists, but by surgeons. This recognition is, however, of comparatively recent date, as the parathyroid glandules were rediscovered by Gley only in 1893.

In *Surgery, Gynecology and Obstetrics* for May, 1910, Jasper Halpenny writes on the relationship between the thyroid and parathyroids and reviews recent literature on the subject. Escherich says that tetanoid conditions in children receive their explanation from a study of the pathology of the parathyroid glandules, and Berkeley and others claim therapeutic benefit from the administration of an extract of the glandules in cases of paralysis agitans. The operation for goiter is now being carried on

with a view to avoiding injury to the parathyroid glandules. F. Shepherd of Montreal in the discussion which took place on exopthalmic goiter at the recent meeting of the Canadian Medical Association laid stress on the fact that in operating in cases of Graves' disease his object was to interfere with the parathyroids as little as possible. The trend of present day surgeons, indeed, is to regard the ablation of the whole thyroid as a safe procedure, but to leave the parathyroid glandules intact. Halpenny undertook a series of experiments with the object of confirming, or otherwise, the statements of recent authors as to the functional importance of the parathyroids and their physiological relations to the thyroid gland. The views at present held are that parathyroidectomy is invariably and rapidly fatal, while thyroparathyroidectomy is less rapidly fatal than is ablation of the parathyroid glandules alone.

Thyroidectomy alone, in probably all vertebrates, according to Jeandelize, is followed by a series of chronic nutritional changes, and it is held that, though these two organs are functionally associated with one another, neither one can assume the functions of the other, the parathyroid glandule being regarded as having a more vital function than the thyroid gland. Halpenny is unable to confirm some of the statements regarding the relative importance of the two organs and he considers that many of the practical conclusions drawn therefrom seem premature and unwarranted.

In his service, 12 cats, 25 dogs, and 25 rabbits were operated on. In the first instance, he found that it was extremely difficult, frequently impossible, to perform parathyroidectomy without severe injury to the thyroid gland, and in doing a thyroidectomy the parathyroids were almost invariably injured. Furthermore, Halpenny was unable to confirm the statement that complete parathyroidectomy invariably proves fatal. Again, the generally accepted statement that parathyroidectomy alone is a more rapidly fatal operation than thyroparathyroidectomy does not coincide with Halpenny's results. As to the anatomical and physiological independence of the thyroid and parathyroids which is now the current belief, Halpenny points out that these views have been recently subjected to criticism and the old belief is gaining ground, that there is a definite physiological relationship between the two. The results of Halpenny's series of experiments appear to indicate that, in some instances, each gland is able to assume the functions of the other to a greater or lesser extent. The writer concludes that though the parathyroids are not rudimentary thyroids, the whole apparatus is essentially one, and its functions have to do with metabolism.

THE ESTABLISHMENT AND MANAGEMENT OF PUBLIC HOSPITALS.

Because of the very great and rapidly increasing cost of caring for the sick in their homes, due to increased expenditures for nursing and necessary medical attendance, as well as the increasing difficulty in securing sanitary conditions, proper diet, care, and facilities for operation and postoperative care in individual homes, the care of the sick is becoming increasingly a hospital problem. This tendency is further augmented by the fact that people tend more and more to dwell in cities and villages, in quarters so crowded that proper care of sick persons is quite impossible. It is also found increasingly necessary to move many cases from homes to hospitals for the conservation of the health of those remaining at home. It is, therefore, becoming more and more apparent to those who are interested in the problems of public health that hospital facilities for the care of the sick poor must be greatly increased.

In order to meet this necessity a bill was passed at the recent session of the New York Legislature and signed by Governor Hughes on June 21. The bill was entitled "An act to amend the general municipal law in relation to the establishment and maintenance of public general hospitals for the care of the sick." It was prepared by the Standing Committee on Hospitals of the State Charities Aid Association, after an examination of existing legislation of this and other States, relative to the establishment of public hospitals and after a careful study on the part of the committee of the problem of hospital control and management. The purpose of the law is twofold: (1) To facilitate the establishment of public general hospitals by the cities, villages, and towns of the State; (2) To provide a well thought out plan of control and management of such hospitals, and to secure some uniformity of method where no system exists at present. The committee found that the charters of most cities and villages and the general laws relating to them are such that it has been necessary, whenever a city or village desired to establish a public general hospital, for it first to secure a special act from the legislature giving it the authority to do so. This in some instances has resulted in vexatious delays and tends to discourage the development of such hospitals. It is evident, however, that, when it becomes necessary for a city or village to pay considerable sums for maintaining poor patients in hospitals, it is ultimately the best policy for that city or village to establish a hospital of its own, where the expenditure of these funds will be entirely under public control and the hospital under public management.

It was to remedy this defect in the general hospital law and to make it comparatively easy for the small towns to establish and maintain a hospital adequate to its needs that the committee undertook a study of the question and a drafting of the bill, which has just become a law. The bill seems to have been very carefully drawn after a profound study of the question, and it contains promise of a marked betterment of the conditions hitherto existing.

The Treatment of Hemophilia Neonatorum.

Until within the past two years the disease of the newborn known as hemophilia neonatorum, and characterized by general diffuse hemorrhage during the first few days of life, has been an almost universally fatal condition. The bleeding being rapid and due to some chemical change in the

blood which prevented clotting, efforts were made to control the hemorrhages by the administration of calcium, gelatine, and other general hemostatics, but with very slight effect. The injection of saline solution, while temporarily refilling the depleted circulation, in no way stopped the course of the disease, and inoculation with large amounts of animal blood or serum was found to produce a disastrous hemolytic action, causing more damage then benefit. The first real advance was made two years ago, when Carrel, through a delicate technique developed by animal experimentation at the Rockefeller Institute, saved the life of a moribund infant five days old by anastomosing the child's popliteal vein and its father's radial artery, and then transfusing human blood into the exsanguine infant. The new blood not only replaced that which had been lost but so changed the quality of the infant's blood that no further hemorrhage occurred. This operation has been performed a number of times since then by various operators, often with excellent results. It has, however, two serious drawbacks, the difficulty in obtaining a suitable and willing donor, and the extremely delicate technical skill required to operate on the small blood-vessels of the new-born infant. In the *American Journal for the Medical Sciences* for June, 1910, J. E. Welch reports the results of a procedure which in many ways eliminates these drawbacks. Instead of transfusing blood directly into the infant he has drawn off the blood from the donor into a sterile flask, allowed it to clot, and then injected subcutaneously the separated serum in doses of 10 c.c. at a time, the injection being repeated in severe cases as often as every two hours. His results have been all that could be desired. Whereas of eighteen cases of hemophilia neonatorum treated in the New York Lying-in Hospital before this treatment was undertaken seventeen died, the eight children treated with human blood serum have all made rapid recoveries. The reason why the serum should so quickly stop the hemorrhagic tendency he does not attempt to explain, but the fact that he has obtained a cure in eight successive cases of a disease usually considered hopeless is sufficient to encourage others to repeat the method.

The Trachoma Bodies and the Gonococcus.

The discovery comparatively recently of the small granular bodies within epithelial cells in the eye secretions in acute cases of trachoma, variously called trachoma bodies, chlamydozoa, and cell inclusions, and their artificial inoculation into the conjunctivæ of monkeys, have given a great stimulus to the study of this highly infectious disease of the eye. One of the first results of this impetus was the finding of similar bodies in the eyes in supposedly nonspecific blennorrhea neonatorum. This was quickly followed by their isolation from the vagina of the mothers of such infants, and from the urethral secretions of men suffering from non-gonorrheal urethritis. The proof seemed almost conclusive, therefore, that all of these conditions were most closely related, and taken together comprised a new infectious venereal disease. In the *Deutsche medizinische Wochenschrift* for June 9, 1910, Herzog throws doubt upon this venereal disease being a new discovery at all, and he states definitely that the so-called trachoma bodies are but involution forms of the gonococcus. For this belief he gives several reasons. He has produced morphologically identical bodies by prolonged cultivation of a pure culture of the gonococcus. He has found typical trachoma bodies in the eye secretions of undoubted cases of gonococcus blennorrhea making their appearance during the subsidence of the acute stage of the disease. In fresh cases of trachoma he has found intracellular organisms which appear to be transition forms morphologically lying somewhere between the typical gonococcus and the trachoma body. Finally he has tried the experiment of inoculating a pure culture of the gonococcus, isolated from a twelve-day-old gonorrheal urethritis, into the conjunctiva of a blind glaucomatous eye of a man. Fourteen days after the inoculation typical trachoma bodies were isolated from the secretions of the patient's conjunctiva. The relationship between gonorrhea and trachoma has been suggested by various authors for many years, but no satisfactory proof of the unity of the two diseases has as yet been produced. The work of Herzog does not settle the question beyond controversy, but it offers a valuable suggestion for future research.

News of the Week.

Rupture of Reciprocity Between New York and New Jersey.—The following letter has been sent by Dr. H. G. Morton, Secretary of the New Jersey Board of Medical Examiners, to Mr. Augustus S. Downing, First Assistant Commissioner of Education of New York State: Dear Sir—Your communication of June 23, in reply to mine of the 22d ult., in reference to the annulment of the reciprocal relations in medicine between the States of New Jersey and New York, has been duly considered. In reply I am directed to advise you that this Board feels that the Board of Regents of New York, in rescinding the reciprocity agreement between these States acted without sufficient consideration of the subject, or due regard for the interests of the medical profession. This reciprocity agreement was reached after long and thorough investigation of the medical statutes of both States on October 25, 1906, and went into effect January 1, 1907. The medical statutes of New Jersey have not been changed in any respect since that time; nor have the standards of examinations been lowered. This agreement has worked satisfactorily in the past, is highly prized by the medical profession of both States, and promotes the interests of the public and of the profession. This Board, therefore, requests that the annulment be reconsidered and the reciprocity agreement renewed. Knowing that the Medical Societies of the State of New Jersey are opposed to indorsing the license of any State which refuses to indorse the license of New Jersey, the State Board of Medical Examiners of New Jersey this day passed the following resolution: Resolved, That on and after November 2, 1910, further indorsement of the certificates of medical license issued by the State of New York would be discontinued, unless the agreement of reciprocity between the States of New York and New Jersey is renewed in the interim.

Hoffman Island Hospital.—The new hospital on Hoffman Island in lower New York Bay, which the State is just completing for the accommodation of cases of contagious disease coming into the port of New York, was opened for inspection on July 3. To provide sufficient area, Hoffman Island has been

enlarged, by pumping up sand from the channel and filling it in behind retaining walls, to nearly three times its original size. Hospital buildings and pavilions to accommodate 250 patients will soon be ready for occupancy. Provision has also been made for the relatives and friends of patients, and the grounds have been improved with grass, trees, and shrubs. Fresh water is obtained by means of an artesian well, 2,500 feet in depth, with a capacity of 45,000 gallons per day. One of the most interesting features in connection with the new hospital will be the school for instruction in communicable diseases. It is planned to assign two health officers from different parts of the State to the hospital every four days for the study of contagious diseases, and the latest and best methods of treatment. A permanent group of State officers will be maintained to carry on the work of instruction, and a training school for nurses will also be maintained. The hospital is intended only for the milder contagious diseases, and the rare cases of plague, smallpox, yellow fever, etc., which come into the port will, as heretofore, be sent to Swinburne Island.

Fire in a Hospital.—Two fires occurring on successive days recently in the Kings County Hospital, Brooklyn, N. Y., are now under investigation by the Fire Marshall, suspicions of incendiarism having arisen. The first fire, on the night of July 4, was traced to several old mattresses in the basement of Annex I, used as a dormitory for the orderlies of the hospital, and was extinguished with but little difficulty. The second, however, which apparently originated in the same place, damaged the building to the amount of $2,000, and excited the 1,500 patients of the institution, besides causing almost a panic in the Long Island State Hospital for the Insane, situated across the street. The patients in the tuberculosis pavilion, only about fifty feet from the burned annex (were ordered to dress and be prepared to leave, but the fire was fortunately got under control and confined to the building in which it started.

Municipal Bath.—Plans for the new municipal bathhouse at Coney Island were filed recently. A three-story building is to be provided for, having a frontage of 65 and a depth of 400 feet. Locker accommodations for 5,563 men and dressing-rooms for 1,293 women will be provided.

Bacteria in Croton Water.—Dr. Ernst Lederle, Commissioner of Health of New York, is reported to have called attention, recently, to the extraordinary precautions necessary to safeguard the Croton watershed. Following heavy rains recently there occurred a large increase in the number of bacteria in Hunter's brook, which supplies Croton Lake. Although all of this watershed is not owned by the city it has been thoroughly inspected and generally cleaned up; imperfect sanitary arrangements in the laborers' camps have been corrected, and safe methods of disposing of refuse provided; and the city water is said to be again perfectly safe, containing only a normal number of bacteria.

Frozen Eggs.—The confiscation of 25,000 pounds of frozen egg products, said to be the largest seizure ever made by the Government, took place in Brooklyn, New York, on July 7, by order of the Department of Agriculture. Examination of samples of the eggs made by the chemists of the department resulted in the estimation that each gram of the egg product contained 30,000,000 organisms, some gas-producing, and some of the streptococcus group. The desiccated eggs were forwarded by a packing house in Chicago. Permissive to destroy the product according to law has been granted, and unless a legal fight is made the seized eggs will be disposed of by the Health Department.

Five Generations.—Ignatius Neggersmith of the Bronx, New York, who died recently at the age of 101 years, left descendants to the fifth generation, five children, 37 grand children, 27 great-grand children, and four great-great-grand children surviving him.

Miss Mary E. Samuels, supervisor of nurses at the Roosevelt Hospital, New York, has recently resigned her position after many years of service, and, it is understood, will retire from active work. Miss E. B. Ross has been appointed to fill her place.

Summer School.—The College of Physicians and Surgeons, Columbia University, New York, opened its summer session on July 6. Courses are given in bacteriology, clinical pathology, physiological chemistry, and physical and medical diagnosis. The session will close on August 17.

Hospital Attendant Punished.—Convicted of cruel and inhuman treatment of a patient in the Government Hospital for the Insane in Washington, D. C., an attendant at the hospital, has been sentenced to serve six months' imprisonment, without the option of a fine.

Nurses Graduate.—At the Nassau Hospital, Mineola, N. Y., commencement exercises were held on July 6, ten nurses receiving diplomas on the completion of their training.

Marriages in New York.—Statistics of the Department of Health recently given out show that during the first six months of 1910, 22,035 marriages took place, an increase of more than 2,000 over the same months of last year.

Market Licenses.—In an effort to improve the sanitary conditions of Washington Market, New York, the Comptroller has revoked some sixty-three licenses for stands. He promises to clear the sidewalks of all encumbrances, thus permitting both order and cleanliness. The merchants will be restricted entirely to the stands.

Graduating Exercises.—Twenty students of the Maine Medical School, Bowdoin College, Vermont, received their medical degrees recently. One student from Cuba and another from Stockholm, Sweden, were included among the number.

Medical Alumni.—The following officers of the University of Vermont Medical Alumni were elected at a meeting on June 28. *President,* Dr. W. N. Bryant, '73, Ludlow, Vermont; *Vice-President,* Dr. James M. Fay, '75, Northampton, Mass.; *Secretary and Treasurer,* Dr. F. K. Jackson, '99, Burlington, Vermont.

Dr. A. F. King of Burlington, Vt., was the guest of honor at a dinner given recently by his colleagues to celebrate his completion of 40 years of service as professor of obstetrics and gynecology in the University of Vermont College of Medicine. About forty physicians were present.

Prof. Sir William Crookes of London, England, the well-known chemist and authority on sanitation, has received the Order of Merit from King George V. Thomas Hardy, the novelist, was also gazetted a member of the order at the same time.

Dr. Charles M. Rosser of Dallas, Tex., spoke at a meeting of the Taylor County (Texas) Medical

Society on June 27, on Cancer of the Uterus. On the same night a dinner, at which covers were laid for thirty, was given in honor of Dr. Rosser at the Hotel Grace, in Abilene.

Dr. William Stockwell has been appointed resident physician and medical superintendent of the State Tuberculosis Hospital, opened on July 1, at Shelton, Conn. Dr. Stockwell was graduated from the medical department of the University of Pennsylvania in 1904.

Charitable Bequests.—By a decision of the Supreme Court of Pennsylvania the validity of the will of the late Anna T. Jeanes is sustained, and the following bequests became operative: The Incorporated Trustees of the Philadelphia Yearly Meeting of Friends for the establishment and assistance of hospitals and infirmaries, $250,000; the Joint Committee of the Quarterly Meeting House for Aged and Infirm Friends, for the establishment of a hospital for cancerous and nervous ailments, $200,000; the Women's Hospital, $64,000; the West Philadelphia Hospital for Women, $10,000; the Hahnemann Hospital, $10,000; the Philadelphia Home for Incurables, $10,000; the Women's Homeopathic Hospital, $10,000; the Pennsylvania Hospital, $10,000; the Red Bank Sanitarium, $5,000.

By the will of Mrs. Margaret M. Coakley of New York, St. Joseph's Hospital for Consumptives and the Cancer Hospital at Hawthorne each receive $500. St. Luke's Hospital, New York, receives a bequest of $7,500 under the will of the late Mrs. Mary E. Leavitt of that city, who died on June 20. By the will of the late Erskine M. Phelps, the Hahnemann Hospital, of Chicago, receives $25,000, while another $75,000 is left for the benefit of the nurses of the institution.

Berkshire District (Mass.) Medical Society.—A meeting of this society was held in Pittsfield, Mass., on June 30, when a paper was read by Dr. C. H. Bangs of Boston, secretary of the American Health League. A joint meeting of the Berkshire District and the North Berkshire medical associations will be held on August 25.

The Lake Keuka Medical and Surgical Association will hold its eleventh annual meeting at Grove Springs, Lake Keuka, New York, on Thursday and Friday, July 21 and 22, 1910, under the presidency of Dr. Robert M. Elliott of Willard, N. Y.

The Associated Physicians of Long Island held a meeting and clambake at Smithtown, Long Island, on June 25. The guest of honor was Dr. Harvey, who spoke on "Preventive Medicine from a Chemical Standpoint." The president of the association, Dr. James R. French, also spoke, his subject being "The Relation of the Medical Profession to the Public." The next meeting of the association will be held in Oyster Bay in October.

Reduction of Infant Mortality.—Dr. Joseph S. Neff, Director of Public Health and Charities, of Philadelphia, has appointed one supervising nurse and eight assistant nurses, whose duty it shall be to visit mothers in their homes and aid them in the care of their infant children during the summer.

Smallpox in Walden.—Two cases of smallpox have been reported in Walden, New York. The first patient, the health officer of the town, is thought to have contracted the disease while on a visit to the Immigration Bureau in New York.

Cholera in Russia.—The training ship *Newport* of New York has altered its itinerary on account of the presence of cholera in Russia and will not stop at Kronstadt as originally planned. Two fatal cases of the disease have also been reported from Berlin.

The Healthy Philippines.—The Bureau of Insular Affairs reports that the death rate among the more than 8,000 Government employees in the islands for the quarter ended March 31 was 6.9 per 1,000 per year. Of these employees some 3,700 are Americans, including the officials and employees of the insular, provincial, and municipal governments, and the police and fire departments of Manila.

Obituary Notes.—Dr. Asahel Norton Brockway of New York died on July 4 at Clinton, N. Y., where he had gone to attend the commencement exercises at Hamilton College, from which he was graduated in 1857. Dr. Brockway received his medical degree from the College of Physicians and Surgeons, New York, in 1861, and after an interneship at Bellevue Hospital, served as assistant surgeon in the United States Army until the close of the war. He was 74 years old.

Dr. Frederick A. Lyons of New York died at his home on July 5. Dr. Lyons was born in Toronto, Canada, in 1854, and was graduated from the College of Physicians and Surgeons, New York, in 1876. He was at various times connected with Bellevue Hospital, the New York Foundling Hospital, and the New York Throat and Nose Hospital, and was a surgeon of the Fire Department from 1885 until his death. He was a member of the New York County Medical Society, the New York Medico-Surgical Society, and the American Academy of Medicine, and was for several years editor of the *Hospital Gazette*.

Dr. Clement Bloch of New York died at his home on July 3, aged 47 years. Dr. Bloch received his medical education at the University of Koenigsberg, Germany, from which he was graduated in 1890. He was a member of the German Medical Society.

Dr. R. J. Walker of Toledo, Ohio, died suddenly on July 7, aged 48 years. Dr. Walker was graduated from the Columbus Medical College, Columbus, Ohio, in 1885, and was a member of the County and State Societies.

Dr. Frank L. Wood died at his home in Long Beach, Cal., on June 28, aged 36 years. Dr. Wood was graduated from the Harvard Medical School in 1874, and was a member of the County and State Societies.

Dr. Willis S. Anderson of Detroit, Mich., was drowned on June 27. Dr. Anderson was born in 1868, was graduated from the College of Physicians and Surgeons, New York, in 1891, and was a member of the American Medical Association and of the State and County Societies.

Dr. Robert Emmet Burke of Louisville, Ky., died at his home on June 28, aged 26 years. Dr. Burke received his degree from the Medical Department of the University of Louisville, from which he was graduated in 1905.

Dr. John Winthrop Spooner of Hingham, Mass., died at his home on June 26, of cerebral hemorrhage. Dr. Spooner was born in 1845, and was graduated from Harvard University in 1867, and from the Harvard Medical School in 1871. He was a member of the American Medical Association, and of the County and State Societies, and was at one time president of the Medico-Legal Society.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

BIRTHDAY HONORS—SYNTHETIC HYPNOTICS—MALARIA—HEALTH OF INDIA—DENTISTRY FOR SCHOOLS—AMBULANCE WORK—SIR A. KEOGH AT ST. THOMAS'S HOSPITAL—OXFORD'S ELECTRIC LABORATORY—MEDICAL MISSIONS—OBITUARY.

London, June 24, 1910

This being the day set apart for the celebration of the late King's birthday, a long list of honors and promotions conferred on the occasion is issued this morning. Seven peerages, twelve baronetcies, and a great number of knighthoods and promotions in the various orders mark the occasion, and the medical profession is not overlooked. Sir Walter B. Foster is made a Baron of the United Kingdom, and so we have another medical lord. It is true the ex-professor of medicine deserted the profession for politics, in which he obtained ministerial rank, and his present promotion is the reward of placing his seat in parliament at the disposal of a defeated minister at the last election. But his medical record is good, and he has always evinced an interest in the welfare of his profession.

A baronetcy is conferred on Dr. F. H.. Champneys, obstetric physician to St. Bartholomew's Hospital, and chairman of the Midwives Board. Among the new Knights are Dr. A. H. Downes, senior medical inspector for the local government board; John Fagan, F.R.C.S.I., Consulting Surgeon Royal Belford Hospital; John Lentaigne, President of the Royal College of Surgeons in Ireland; Dr. Caldwell McVail, Crown Member of the General Medical Council and of Glasgow University Court; Dr. B. M. Simon, of the Birmingham General Hospital; Dr. H. S. Lunn and Dr. George Hastings of London.

Among Indian orders, Surgeon-General C. P. Lukis, M.D., receives C.S.I. Inspector-General R.. Macrae gets a C.I.E. Surgeon-Lieutenant-Colonel Crooke-Lawless, Surgeon to the Viceroy, is promoted to the knighthood in the same order, of which he was companion.

Besides all these there are numerous steps in rank in the orders of the Balk, St. Michael and St. George, the Victorian and Indian service. Among them are the names of Inspector-General Porter, Surgeon-General Sloggett, Surgeon-General O. E. P. Lloyd, V.C.., Dr. Hodges, P.M.O., Uganda.

The medical department in the territorial force is also recognized in the appointments of Col. Andrew Clark, F.R.C.S., as Honorary Surgeon, and Col. Blandford, Honorary Physician to H. M. the King.

Among the synthetic remedies that have come so extensively into use, the hypnotics are of special interest. Meyer has just forwarded the hypothesis that chemicals soluble in fats or fat-like bodies have a narcotic effect on living protoplasm. Then the most powerful hypnotic would be that having the greatest coefficient of fat solubility. To the practitioner questions of this kind possess a certain interest, but the majority are probably more inclined to compare the effects of the several hypnotics as inducers of sleep. This was the course of a discussion at the Edinburgh Medical Society on the 1st inst., which Dr. Boyd opened. He regarded amyline hydrate and chloralamide as the best mild hypnotics. The former in doses of ½ to 1 dram was not depressant and he had seen no bad effects from it in cardiac cases. The latter acted well, but sometimes there was a latent period before the action began. It should be given dissolved in alcohol, or better still in sp. etheris. nitr. Of stronger hypnotics the safest was paraldehyde, but its taste was a great objection; it was best given in an enema, well diluted, in doses of 2 to 4 drams, which produced sleep in about 15 minutes. It was not suitable for alcoholic subjects. Sulphonal was toxic and cumulative, and he would exclude it from use. Bromural suited emotional patients. As to still stronger drugs, he said, chloral was now generally disused. Veronal was popular but dangerous; in large doses fever, vertigo, etc., were apt to occur. Prolonged use might bring on peripheral neuritis or ataxia. Other dangerous drugs were isopral, chloralose, sulphonal, tetronal and chloral-urethane.

A combination was usually better than a single hypnotic, and when used for a length of time a frequent variation tended to minimize the danger of habit. Another important truth was always to give hypnotics in solution. It was desirable that further restrictions should be placed on the sale of these drugs which was now carried on to a dangerous extent, as many deaths had in consequence occurred.

Dr. Clouston endorsed the value of combination. It was important to consider whether an immediate or a gradual effect was desired. A small dose of sulphonal at 9 p. m. and one of veronal at 10 p. m. was better than a large dose of either. Bromide was a good adjuvant to hypnotics and sedatives; 20 grains added to a dose of paraldehyde gave sleep at once and a quiet state the next day. He disagreed with Dr. Boyd as to sulphonal, of which he found 10 grains with 20 of bromide most valuable in senile excitement bordering on insanity.

Dr. Robertson of Morningside agreed as to combining the drugs. He often gave a dram of bromide potassium at 7 or 8 P.M., and when it began to act, about 10 P.M., a dose of paraldehyde in bed. He discarded veronal long ago. As to trional, it produced degeneration of nerve cells.

Several other speakers agreed as to the value of combination. One remarked that it was usual to combine purgatives, and for the same reason one hypnotic might well supplement another. Change of air and diet were also discussed in relation to insomnia and drugs. A combination of a diaphanetic with a hypnotic was also recommended. Alcohol was said to be a good solvent, as it dilated the capillaries, but spirits of nitre was still better. In no case should hypnotics be given undissolved. For this reason the sale of tablets was condemned as well as for the other objections mentioned.

Resuming my notes on Major Ronald Ross's lectures on malaria, which were illustrated by lantern slides of parasites and of victims, I may say that he dated the birth of modern pathology at 1850 and its progenitors Pasteur, Koch and Lister. Lavaran in Algeria and Golgi in Italy proved that malarial fever began at the moment when the spores of the parasite separated by fission. It became important to estimate the numbers of parasites, and he calculated that there were 15 million millions of blood corpuscles in a man, and a large number were infected in a patient. To examine closely one cubic millimetre of blood took about 12 hours, and this was only one-threemillionth of the average amount in the body. He was now using a new method of examining it. That was washing out the corpuscles, leaving only the leucocytes and parasites in the microscopic field.

Here I may add that Mr. Murray, the publisher, announces that he will shortly issue an elaborate work on "The Prevention of Malaria," by Major Ross, assisted by twenty leading experts on the subject.

The Public Health of British India During the Year 1908, is the subject of a report by the sanitary commissioner, which has just reached this country and demands grave attention. It deals exclusively with British India, the native states not being included. The population in 1908 was 226,409,600. The deaths exceeded the births, notwithstanding the fact that the deaths from pestilences were very few, not more than 5 per 1,000, although they were above a million in the previous year. But the bright spot of the practical absence of plague is blotted out by the excessive mortality from fever and cholera. In 1908 there were 5,425,372 deaths from fever as against 4,464,881 in 1907; and from cholera, 591,725, as against 408,102. Smallpox also proved fatal to 170,694, as against 103,988 in the previous year.

Medical inspection and treatment of school children, say the educationalists, must include dental work. The London county council has sent an officer to Germany to examine its dental clinics, and he has prepared a report for his committee, in which he extols the methods he saw at work. The importance of the teeth is well understood by both doctors and dentists, and the former are by no means inclined to minimize it. The report named favors the plan of the German "town clinics" he saw at work as the best solution of the question which has been raised, and objects to treatment being handed over to private doctors, which he thinks would interfere with school work. The cost of an extra service is gaily put at little, though the county council may consider it heavy. But they lightly add to the burden of the rate payers in so many directions that they may hesitate. Of course, no one cares for the "private doctors," and the duties of parents are not much considered.

The St. Johns Ambulance Association has declined to assist the government scheme for the aid of wounded

and sick territorials. Questioned in parliament it was deemed that the authorities had the faintest idea of lowering the standard of examinations for "aid detachments." But the fact is that the War Office insisted that nurses should teach, examine and certify nurses for these detachments. But the St. Johns Association requires that for pupils in any subject, first aid, home nursing and hygiene, sanitation, rescue in mines—in any part of their duties in fact—should be taught by one medical man and examined by another who was unconnected with the class. The association has refused to consider a nurse's qualification as equal to that of a doctor and declines to be mixed up in a scheme which ignores the difference. The work is being done by the Red Cross Society, of which the London branch is making an urgent appeal for funds.

Sir Alfred Keogh yesterday distributed the prizes at St. Thomas' Hospital, and gave a vigorous expression to his views on medical education in London. In the clinical work nothing was wanting, but the preliminary scientific teaching was inferior to that of the Provinces. What London wanted was a real teaching university, to grant a good degree after a good examination. The present university might be an Imperial institution for examining, but it was not a London university in the true sense.

The new electrical laboratory—the generous gift of the Drapers Company, erected at a cost of £23,000, was presented to Oxford University on Tuesday in the presence of a distinguished gathering by the Master of the Company, Mr. K. R. Fletcher, B.A. of New College, on whom the degree of D.C.L. honoris causa was conferred with the usual ceremony. The same company has presented equally generous gifts to other departments of the university, and with admirable impartiality has done as much for the University of Cambridge.

The World Missionary Conference has been sitting at Edinburgh all the week and has been numerously attended. Medical missions have been discussed from various points of view, and many have urged that all missionaries ought to have some medical training, especially those sent to districts devoid of doctors.

Inspector-General T. Bolster, R.N., has died at the age of 65. He qualified with two Dublin colleges in 1866 and entered the navy the next year. He reached the rank of deputy-inspector-general of hospitals and fleets in 1896 and became inspector-general in 1901, retiring in 1903.

Dr. Claud Muirhead, consulting physician to the Edinburgh Royal Infirmary, died suddenly on the 22d inst., in his 75th year. He took his M.D.Ed. in 1862 and became F.R.C.P. in 1865. Besides the physiciancy of the infirmary, which he held for the full period, he had a number of other appointments in the city. He contributed to the *Edinburgh Medical Journal* and the *Edinburgh Hospital Reporter*, "Relapsing Fever in 1870"; also on "Enteric Fever," and on a number of other subjects.

UNBOILED CONDENSED MILK AS A SOURCE OF SUMMER DIARRHEA.

To the Editor of the Medical Record.

Sir: When I was in a dispensary in charge of the children's department, some years ago, inquiry as to the causes of summer diarrhea elicited the fact that in nearly every case the child's principal diet consisted of condensed milk diluted for use with warm water. In the course of years this became a standard question. The mothers were then advised to boil this mixture as the, for these people, simplest and yet complete sterilization. The objections to feeding boiled milk were not much heard of at that time, and then too they are so easily overcome that the writer has continued this simple but complete method of sterilization in preference to the cumbersome pasteurization with incomplete sterilization.

Incidentally, a simple method of testing milk for its quality may interest your readers. It consists in setting aside in a living room an ordinary drinking glass, wider at the top than at the bottom, filled with milk, and covered with anything, until it has congealed; in summer about one day, in winter two. The milk now presents in one distinct layer its cream on top of the congealed portion, and if good no water underneath; the poorer milk may, however, show up to half a teaspoonful of water, but more water than this is sure not to have come from the cow.

Elimination of Hexamethylenamine by the Mucous Membranes of the Middle Ear and Nasal Sinuses.—W. M. Barton speaks of the application of the drug named in the title of his paper to the treatment of diseases of these organs, and gives the history of several cases of suppurative otitis media. There is also a brief reference to all the criticisms which have come to the author's knowledge since the publication of a previous report on the same general subject. His conclusions are as follows: (1) Hexamethylenamine is eliminated by the mucous membranes of the middle ear and accessory nasal sinuses (the remedy is given internally in doses one-half to one gram in the course of the day.) (2) Judging from the limited data at hand, it would appear that the drug is of considerable value in cases of acute suppurating otitis media and sinusitis. The chronic forms are apparently benefited. (3) Upon a priori grounds it may be fairly assumed that the remedy may prove to be a valuable prophylactic in those diseases commonly attended by otitis media, perhaps also as a prophylactic to be used prior to surgical operations upon the middle ear, mastoid, and nasal sinuses.

New York Medical Journal, July 2, 1910.

High Frequency Currents in the Treatment of Arteriosclerosis.—After discussing the physics of the high frequency current, T. E. Satterthwaite passes on to its consideration in arteriosclerosis. He figures the apparatus he prefers and which he has used with considerable success during the last nine years. In his experience a diminution in arterial pressure is the regular sequel to the use of the current in the condition named, but the application should not be protracted beyond the time at which the pressure falls to normal. Such protraction might be harmful. The currents alone are not uniformly permanently effectual. While they reduce pressure they may be inhibited in their effects by errors in diet, constipation and various other causes. But the reduction once obtained, it may continue for as long a period as three years. The author says that while the pressure may not be reduced at each sitting there is, notwithstanding, a progressive fall in all instances as the weeks go by. It has sometimes seemed good to him to use the faradic current as an adjuvant. Intestinal atony is sometimes curiously enough a complication of arteriosclerosis. Then the faradic current applied to the abdominal walls may be very helpful to relieve the constipation. In addition he uses as the case indicates mercurials, iron, and the iodides. A course of the iodides is to be followed by a course of iron. In very old people he finds that small doses of arsenic are better than iron.

A Few Observations on the Prostatic Urethra.—J. A. Hawkins refers to several personal cases. He dwells especially on contraction of the internal urinary orifice, suppurative lobular prostatitis and the verumontanum. Suppurative prostatitis is responsible for many cases of "morning drop." Enlargement of the verumontanum with spasmodic contraction of the posterior urethra prevents all pus from passing into the bladder, and it seeps along the urethra to the external meatus. An infected lobule becomes filled with pus caused by its duct becoming plugged and from prostatic muscular contraction or bodily exertion this plug is forced out, allowing the pus to flow into the urethra. Especial attention is called to diseased conditions of the verumontanum. When the deep urethral tube is passed, if the urethra is fairly normal, there is usually no bleeding, but if inflamed the blood will soon ooze into the tube. When inflamed the verumontanum bleeds in proportion to the degree of its engorgement, and as it bobs out into the fenestra of the tube looks very much like an exposed glans clitoridis. Pus is frequently seen in the mouth of the utricle, which is not infrequently seen apparently closed, with the secretion showing through, very much resembling a salivary ranula. This secretion as soon as expressed gathers at the fenestra, solidifies, and resembles slightly softened gum arabic. The treatment in all these cases consists in the judicious local application of nitrate of silver. Other preparations may suffice, but the nitrate is the best of all.

Erroneous Deductions from Physiological Experimentation with Ergot.—A. T. Livingston, who has written several valuable articles on the effects of ergot, insists that in all cases the drug should be given by hypodermic injection. It goes without saying that ergot must be distinctly contraindicated in many states of disease if it uniformly "brings about a long enduring contraction of the walls of arterioles" or produces "powerful and persistent

contraction of bloodvessels." Such effects imply great increase in blood pressure which, in thousands of cases, would be a catastrophe. The truth is that in the applications which the author has made it has more often lowered than raised blood pressure, has calmed tumultuous heart action, softened the hard and bounding pulse, produced calm in place of high tension and excitement, dissipated states of congestion in brain, lungs, abdomen, and pelvis, aborted inflammations, relieved aphasias, promptly ameliorated acute paralyses, quickly terminated the initial chill of developing fevers, abolished pain due to congestion, and even the pang of angina pectoris has promptly yielded to its magic. The truth is, also, that only the clinician who has made large use of ergot and in a great variety of diseases can have even an approximately just conception of its true effect. As to the action of ergot upon the uterus there are two important considerations: First, a changed state of the womb fiber, either pathological or physiological; the latter, like the former, being extended in equilibrium length, and second, the relation, in time, of the periods of especial normal wave (rhythmic) movement to the application of the stimulus. The only instances, five or six, in which the author has produced uterine cramp with ergot were when he gave it at the period of menstruation. Those periods during gestation at which the woman would have menstruated, if she were not pregnant, at which there is an increase of rhythmic movement and the final menstrual cycle of pregnancy and parturition, are the periods when ergot will most likely demonstrate its energy upon the uterus. Except during these cycles of movement, or in states of pathological fiber the uterus is not likely to be affected by any ordinary dose of ergot; especially is this true if there exist elsewhere in the subject areas of abnormal tissue, which would indicate the administration of the drug. With the exception of the consideration which should always be given to the gravid womb, he does not know of any positive contraindication to the hypodermic application of ergot, in reasonable dosage, to any subject in whom exists such abnormal vital contractile tissue as he has before indicated.

Journal of the American Medical Association, July 2, 1910.

Dermatology as a Specialty, and Its Relation to Internal Medicine.—Grover W. Wende makes a plea for the closer relation of the specialty of dermatology to the general field of internal medicine. He believes that the period of infancy of dermatology, a period devoted to the collection of observation and facts, is passing, and that some attempt at the correlation of these facts must be attempted if confusion is to be avoided. The specialist is not equal to this difficult task of correlation except as he cooperates with the general profession. Many crude and mistaken notions on the subject of skin diseases are still prevalent, not only with the laity but also with many physicians, and are the cause of much needless suffering and harm; and only a close professional relation between the dermatologist and the general practitioner will serve to throw light over these old superstitions. As a few among the numerous points of contact between dermatology and internal medicine the writer instances the exudative erythemas, syphilis, leprosy, pellagra, diabetes, punctate telangietases, eczema and psoriasis, parasitic skin diseases, drug eruptions, and the eruptive fevers.

Experiences with the Duodenal Contents.—Max Einhorn gives a table of results of forty cases of examination of the duodenal contents, and calls attention to the fact that this field is entirely new and hardly yet invaded, and further work in it should yield much of value not only with regard to diagnosis but also for treatment. The method of examination is described, and attention called to the following points: Among the seven cases of achylia gastrica trypsin was absent twice and once was only very weak, whereas steapsin and amylopsin were present. An admixture of mucus with the duodenal contents occurs in two ways and is probably of some significance. The mucus may be evenly and intimately mixed with the contents, or it may appear at intervals in the relatively clear contents of the duodenum. The latter would point to the origin of the mucus from the duodenum, whereas its intimate admixture would point to its origin either in the pancreas or the bile passages. Presence of mucus in conjunction with other clinical symptoms (diarrhea, distress some time after meals) would lead us to think of duodenal catarrh. Occasionally we obtain on aspiration of the duodenal contents at first only a clear or slightly amber-colored fluid. It is of alkaline reaction and contains the pancreatic ferments. Usually after waiting a short time and after repeated aspirations a golden yellow fluid (containing bile) appears. If bile is present in the duodenal contents a complete occlusion of the common bile-duct can be excluded. If the bile is entirely missing and pancreatic juice is present, it points to the seat of the obstruction above the common duct.

Inguinal Hernia Following Appendectomy.—Alanson M. Pond reports a case of inguinal hernia following removal of the appendix. He states that the sequelæ of all abdominal operations are increasing, and that this is not wholly due to the increase in the number of operations, but partly to the increase in the number of men who attempt surgery, and is purely a matter of personal equation—of either ignorance or disregard of surgical or anatomic principles. When the operation is dictated by a thorough knowledge of surgical pathology and directed by a perfected mastery of surgical anatomy, the results, both immediate and remote, were never so satisfactory as they are today. The percentage of inguinal hernia after appendectomy is not large, but if the accident occurs at all it is too large, as it can be prevented by sufficient surgical knowledge and proper surgical precautions.

Hyperemia Treatment in Infections of the Breast.—Bertram M. Bernheim claims for his treatment of breast infection that if the patient is seen early enough and pus formation has not started, abscess formation can often be prevented by the institution of cupping for from fifteen to forty-five minutes daily, the breast between treatments being put up in a wet boric dressing, and nursing stopped. If an abscess has already formed, a wide incision is made followed by drainage with iodoform gauze, and the cup is not used until twenty-four hours have elapsed. At the end of the cupping the whole breast is put up in wet boric gauze and very loosely bandaged. The advantages claimed for the method are almost absolute freedom from pain during the whole course of the disease, better preservation of the gland function, the minimum of scar-formation, shortening of the length of the disease, and prevention of abscess formation if the case is seen early enough.

The Lancet, June 25, 1910.

Treatment of the Dysphagia of Laryngeal Tuberculosis by Alcohol Injections into the Superior Laryngeal Nerve.—Dundas Grant thinks this therapeutic procedure worthy of careful attention. He records six cases, all with severe pain, which were greatly benefited and in some instances completely relieved by the injections. An ordinary syringe, strongly mounted, is used, with a needle obtusely beveled so as to avoid the danger of puncturing a vessel. He uses a solution made of two grains of Beta-eucaine in an ounce of 80 per cent. alcohol, and follows Hoffmann's method of injection, viz., the patient is placed in a horizontal position, while with the thumb of the left hand the operator presses the sound side of the larynx toward the middle line so that the affected half projects distinctly. The other fingers of the hand lie on this. The index finger enters the space between the thyroid cartilage and the hyoid bone from without until the patient announces that a painful spot has been reached. The operator now places the index finger on the skin (which has been previously disinfected) in such a way that the point of entrance for the needle lies about at its middle. The needle is pushed in for one and a half centimeters. The distance is marked off on the needle perpendicular to the surface of the body. According to the thinness of the subcutaneous layer of fat the perforation has to be more or less deep. The needle is then carefully moved to seek a spot at which the patient announces that he feels pain in the ear. The syringe filled and its contents warmed to 113° F. is screwed on to the handle and the piston carefully pressed down. The patient feels pain in the ear, the cessation of which he indicates by raising his hand. During the operation he must neither speak nor swallow. If, however, he makes a movement of swallowing the operator must follow the movement of the syringe with a light touch. The injection is kept up until the patient no longer feels the pain in the ear. Then the needle is removed and collodion or sticking plaster is placed on the injection spot without pressure. The average amount of injection is about 2 centimeters.

The Utility of the Autolytic Power of Horse Serum.—The practical utility of this remedy for the purposes indicated is extolled by F. C. Eve from his results with it in two cases of extensive superficial ulceration and one case of severe purpura hemorrhagica. Case I was that of a boy of 6 years operated on for congenital dislocation of the hip by the Lorenz method. He became very thin, developed hematuria and a malignant ulceration of the arm. All these apparently autolytic manifestations were at once arrested by the local administration of horse serum. Conceivably he was sensitized to the formation of these cytolysins by the large hematoma and cell destruction inseparable from the Lorenz operation. Case 2 was a well

nourished boy of 3 years, operated on for non-caseating tuberculous glands of the neck. He did well until the twelfth day, when the wound began to stop its healing and degenerated into a deep, sloughing purulent ulcer. Then the wound was dressed with horse serum soaked gauze and at once began to improve and soon healed. Case 3 was that of an active woman of 75 years, on the inside of whose cheeks and on whose tongue large hemorrhagic spots appeared after the usual symptoms of an ordinary cold. Then petechiæ appeared all over the body and she lost considerable blood from the bowel. Submucous hemorrhage into the laryngeal mucosa caused considerable stridor. Small injections of the serum into the skin over the ribs led to a cessation of the bleeding. It is said that under these general circumstances until blood platelets appear there is always danger of a relapse. Some instructive remarks are added as to the use of the serum in general.

Hypodermic and Intramuscular Inoculation of Bacterial Vaccines as Demonstrated by Experiments with Typhoid Fever.—D. Semple presents tabulated results and says: (1) The immunising response following the inoculation of typhoid vaccine in rabbits as measured by the presence of agglutinins and opsonins in the blood is the same whether the vaccine is given subcutaneously or intramuscularly. (2) In both methods of inoculation the agglutination and opsonic changes when plotted on a chart take similar courses and in both an increase of agglutinins practically means also an increase in opsonins. (3) The intramuscular method of inoculating bacterial vaccines possesses no advantage over the subcutaneous method, and as the latter gives rise to less pain and inconvenience it is to be preferred.

British Medical Journal, June 25, 1910.

The Value of Serums and Vaccines in the Treatment of Disease.—N. Raw discusses this question with reference to acquired immunity and then takes up in turn the antistreptococcic sera as used in puerperal septicemia, erysipelas, malignant endocarditis, acute tonsillitis, diphtheria, tetanus, tuberculosis, and then speaks of the use of vaccines (tuberculin) from human sources for tuberculosis, pneumonia, staphylococcic infections, Coley's fluid and typhoid fever. He considers the vaccine treatment of the latter disease in which Wright was a pioneer as more a prophylactic than a curative measure. The best results are obtained in staphylococcic infections. He is inclined to believe that vaccines do good in pneumonia, but the evidence is still small. In regard to tuberculin from human sources he has used the T. R. in 110 cases, including tuberculous glands in the neck, tuberculous peritonitis, tuberculous joints and sinuses, lupus, tuberculous meningitis, and genitourinary tuberculosis. In the localized forms of the disease, most of which he believes to be of bovine origin and conveyed to children in infected milk, he is convinced that the T. R. has an excellent effect except in those patients in whom there is some pus encysted in the body, whether in the interior of the joint or in a bone under pressure, or as an abscess in a lymphatic gland. In these cases there is a danger of tuberculin causing dissemination of the bacilli, with a resultant blood stream infection. It is a good rule never to give tuberculin if any pus is localized in the body. In many cases a course of tuberculin has had the effect of greatly reducing enlarged tuberculous glands of the neck, by dispersing the periadenoid tissue and causing a general freeing and loosening of the glands themselves, while in some the enlarged glands have entirely disappeared. If, however, there is any tendency to suppuration the glands must be opened, and in all cases the pus should be liberated. He feels convinced, however, that the extensive dissection of glands in the neck is wrong in principle, and sometimes leads to a general tuberculosis which is fatal. In tuberculous peritonitis tuberculin has a splendid effect, and, combined with operation and drainage, many patients have been completely cured. In genitourinary tuberculosis ten or twelve injections of tuberculin have often had an excellent healing effect when everything else has failed.

Ovarian Grafting and Menstruation.—E. S. Chapman says that operation has been successfully done, but that the interesting question at present is this: What actually takes place in a woman in whom both ovaries and tubes have been removed while the uterus has been left in place and in whose abdominal wall one of the ovaries apparently in a healthy state has been implanted. Such a patient after recovery from operation possesses a uterus in a normal position and an ovary in an abnormal position. Is it possible for such a uteroovarian combination to present the congestive phenomena associated with menstruation? He publishes the history of one case in which normal menstruation occurred, accompanied by enlargement of an ovary which had been implanted four and a half months previously. On the basis of this case the author says that the female organism is in the first place under the influence of a toxin the origin of which is at present unknown, but of which the action is elective for the ovary; that the toxin produces an intense congestion of the ovary and perhaps a special metabolism and that then an internal secretion derived from the ovary is formed, which has a special action on the uterus and which determines the discharge of blood. In his own case for a period of four and a half months there were present certain signs, such as swelling of the ovary, flushings and general lassitude, which were evidences of the presence in the organism of a poison having an elective action on the vasomotor system. After this period the grafted ovary had become permeated with vessels from the parent organism, newly-formed vessels had penetrated into the central portion of the ovary and the menstruation, which up to that time had been in abeyance, was influenced by the grafted ovary and occurred again in the usual manner.

A Case of Sleeping Sickness Showing Regular Periodical Increase of the Parasites Disclosed.—The report is made by R. Ross and D. Thomas; their patient was a man of 26 years, admitted to hospital, having acquired the disease in Africa. He was under observation for a period of 73 days. During this time forty-six blood examinations were made, but on several occasions none were made for three or four days in succession, so that, even if the methods of counting had been more accurate, sudden fluctuations might easily have been missed. On admission the blood was reported to contain about 6,000 trypanosomes per cubic millimeter and large numbers, amounting to about 3,000, were found 10 days later and, again, at a third examination one month later. At this time the patient was given the usual treatment with atoxyl and mercury, and received in all ten doses of from two to four grains of the former. Nevertheless, the parasites never fell below 2,000 per mm. It was then found that the atoxyl was injuring the patient's sight, as sometimes happens, and other treatment was substituted. Reference to the statements of the authors shows that during the 73 days mentioned there were eleven distinct rises in the number of the parasites. There were two kinds of rise, viz. high rise and low rise. The regularity in alternation of these two kinds of rises was so well marked as to recall the picture of a double tertian malarial fever and to suggest that two independent sets of parasites might exist in the patient, just as often happens in malaria. A slight rise in temperature was always concurrent with the rise in the number of parasites.

Berliner klinische Wochenschrift, June 13, 1910.

Paratyphoid-A Infection in the Nursling.—Eckert, of Prof. Heubner's Clinic, sums up our knowledge of this subject which goes back some 14 years. We know that these bacteria can set up pseudotyphoid fever, gastroenteritis, meningitis, etc., and that they are invariably to be recovered from the blood. In the majority of cases they enter the system in raw meat, sausage, etc. In most of the older reported cases the germ was *B. paratyphosus-B.*; but the original claim that *B. paratyphosus-A.* was hardly more than a curiosity as a cause of disease has now been superseded. However, the case which is appended is believed to be the first on record to occur in a nursling. The patient was eight months old when he came to the clinic. Four weeks earlier he had gone through a right lobar pneumonia, which later appeared on the left side and was followed by pleurisy. Just before admission meningitis was evident, but whether this was secondary to a purulent otitis media (which was evidently due to infection from coughing) could not be ascertained. The infant lived six days after admission and presented on autopsy purulent meningitis. A bacillus recovered during life by lumbar puncture and after death from the meninges and blood was recognized as the paratyphosus-A. Some enteritis coexisted. The intrathoracic lesions had not undergone resolution and there was bilateral emphysema with hypertrophy of the left ventricle. The relation of the bacillus to the lesions was paradoxical and best explained by the grafting of the paratyphus bacillus on an anteecedent pneumococcus infection; for some pneumococci were cultivated from the blood. The paratyphosus-A was held responsible for the enteritis and probably for the terminal meningitis.

Recognition of the Psychopathic Constitution in the German Army.—According to Staff Physician Stier, the new psychology is being utilized by army medical men in weeding out recruits and soldiers who, by reason of an

inherited psychopathic taint, are rendered less amenable than the average man to military discipline. Neurasthenia is the most common expression of a neuropathic taint and is recognizable by the morbid irritability and the exaggerated mental and physical exhaustibility, by its sensorial and sensible hyperesthesia, its headache and sleep disturbances. The hysterical psychopathic constitution is distinguished by instability in the realm of the affect-life, by disturbances of the ideation and of attention. In contradistinction to neurasthenia, they are somewhat prone to show physical evidences of degeneracy. While neurasthenics can be utilized in certain lines of effort, hystericals should be rejected outright. Those who possess the epileptic constitution are characterized by habitual outbursts of rage and are intolerant to alcohol. These peculiarities may lead to the suspicion of epilepsy, which need not exhibit major paroxysms. There is also the hereditary psychopathic constitution, and the closely related acquired condition, which are characterized by complete psychic disharmony and disequilibrium, affecting the emotions, conduct of life and personality. Superior mental attainments may coexist with gross defects. Physical stigmata are common. The notion of degeneracy naturally stands in close relationship to the moral sphere. More attention than was formerly the case is now bestowed on organic and functional stigmata of degeneration, which are common to most hereditary psychopaths. No heed is taken of some stigmata such as misshapen ears, which are found to have little practical significance. On the other hand, malformation of the head, anomalies of dentition, and of the distribution of hair are of recognized importance. So, also, are malformations of the genitals. Disproportion between age and actual state of development is of value. Of functional stigmata attention is paid to speech defects, squinting of the eyes, and quivering of the eyelids, tic-like movements and disagreeable habits like onychophagy. The manuals in use for selection of recruits have long paid attention to outspoken psychoses and pronounced defects of development; but the kind of material discussed by the present writer is for the most part as yet unincorporated into reference manuals and guides.

Busch's Cosmetic Operation for Facial Paralysis.—Momburg reports a number of cases in which he has made use of this procedure, which, originally devised in 1906, was described before the Berlin Otological Congress last February. The procedure is described by Momburg as follows: A small horizontal incision is made over the malar bone down upon the periosteum and a second one close to the angle of the mouth and parallel with the upper lip. The design of the operation is to do away with the unsightly drooping of the corner of the mouth on the paralyzed side and this is accomplished by passing a double wire of aluminum bronze from one wound to the other so that it forms a loop, with the free ends in the upper wound. By means of traction on the free ends the loop is made to raise the angle of the mouth to a desired height. The wires may then be twisted together and buried. The procedure is purely palliative, for while the wires may remain in place for weeks without causing irritation, the trouble returns with their removal. Many modifications of technique may apply to individual cases. The wires pass through the periosteum of the malar bone and soft parts of the cheek, and Busch introduced them with the aid of a specially devised needle. The operation is performed under local anesthesia.

Münchener medizinische Wochenschrift, June 14, 1910.

Venesection in Circulatory Disturbances and Bloodless Substitutive Procedures.—Von Tabora has to a considerable extent identified himself—in conjunction with his chief, Prof. Moritz of the Strassburg Medical Clinic—with the subject of the unburdening of the venous circulation and the incidental reduction of venous blood pressure, by the combined or alternate use of venesection and the cutting out of the venous circulation of a limb by temporary ligation. When venous stasis is due to uncompensated heart lesions, cardiac stimulants are naturally freely employed. A special phlebotonometer is employed for estimating the venous pressure. It is a self-evident fact, borne out by the author's own statements, that the elaborate manual of procedure involved is of use chiefly in prolonging life in incurable cardiac cases by averting impending edema of the lungs. A question is raised, however, as to the value of the procedures in acute pneumonia. The author hopes to find a definite indication from the venous pressure to interfere systematically in certain cases of the latter disease; and he even believes that he has rescued patients by thus warding off terminal edema of the lungs. He freely admits that such an indication is only exceptionally present in pneumonia. There is no doubt, however, that actual venesection up to 750 c.c. conjoined with temporary ligations of the trunk vein of an extremity (von Dusch's "bloodless venesection") will cause a notable sinking of the venous blood pressure; and if injection of some digitalis or strophanthus preparation is superadded, the unburdening of the venous circulation in venous stasis of cardiac origin is marked and salutary.

Cell-inclusions in Non-gonorrhoic Urethritis.—Siebert refers to the finding by several observers of the v. Prowazek bodies as cell-inclusions in the discharges from blennorrhea neonatorum and gonorrhea in general. The bodies have been found with and without the association of ordinary gonococci, and it has already been inferred that the two types of organism are in some way related. Inoculation experiments have already led to problematical findings. Now, since we meet in practice urethritides which are very resistant toward treatment and yet do not present or at least have ceased to present gonococci in the discharges, a most pertinent question for the investigator relates to the possibility of finding cell-inclusions in such discharges. Lindner having already met this question by finding the cell-inclusions along with granular débris in just such clinical cases, the author has sought to improve his own opportunities for finding such bodies. He selected three cases of urethritis in males which were more or less obstinate, having persisted long beyond the period at which any bacteriologist would expect to find ordinary gonococci. The latter were excluded first by systematic examinations, and it was found as a matter of fact that hardly any bacterial life was present in the secretions.. The author now applied the technique requisite to locate the inclusions, were such actually present, and found them in abundance in the epithelia, though, corresponding to the experience of others, but very sparingly present in the leucocytes.

Family Hemolytic Icterus—Aschenheim refers to the description by French authors of a comparatively new syndrome of family icterus associated with hemolysis and enlarged spleen. During the same period but little has been noted of such an affection in Germany. A general question is incidentally raised as to the relationship between enlarged spleen, hemolysis, and icterus in other diseases, and especially in respect to familial incidence. The author describes a case of chronic icterus, urobilinuria, presence of normal biliary stools, enlarged spleen and liver, which was moreover present in father and son. The case differed chiefly from those described by the French writers in the absence of acute febrile paroxysms. The blood showed the essential fragility of the erythrocytes belonging to the French syndrome. Such a condition is probably described in textbooks with various symptoms and under various designations, which do not refer to essential features. Regarding the hemolysis as a prime factor, the author would introduce a general expression "hemolytic icterus," which may or may not be a familial malady. Naturally such a disease complex would have to be distinguished from or at least contrasted with certain cases of splenic leucemia, with Banti's disease, and other conditions. Icterus alone is hardly sufficient for differential diagnosis, for this may appear as an accidental or terminal symptom in other maladies of this class. The identity of the disease would depend evidently upon its precise seat of origin—and with the association of hepatic lesion with icterus the liver would be the organ first accused—together with the exact order and nature of the blood changes and finally perhaps the tendency to occur in family groups. Typical cases of other affections could hardly be confounded with hemolytic icterus, but it is conceivable that transition forms must be common and perplexing, else the individuality of some of these allied conditions would have been shown long ago.

The Genital Crisis in the New-Born.—Lequeux and Marioton, from the experience of the year 1908-1909, at the Tarnier Clinic, Paris, deduce the fact that the so-called genital crisis of the new-born is comparatively frequent. Out of 1,575 infants born in that year, a crisis was noted in 532. This consists in a swelling of the mammary glands, which is noninflammatory, with a secretion of milky fluid, containing fat globules and epithelial cells. This occurs in both sexes; in boys the testicles, prostate, and tunica vaginalis become swollen and there is secretion; in girls the uterus becomes congested and menstruation may occur; in both there is acne, increase of lanugo hairs, and seborrhea. It occurs about the tenth day, and is entirely physiological, not attended by inflammation, and needs no treatment. It only becomes infected when manipulation causes bacteria to enter from without.—*Bulletin de la Société d'Obstetrique de Paris.*

Book Reviews.

A System of Clinical Medicine. Dealing with the Diagnosis, prognosis, and Treatment of Disease. For Students and Practitioners. By Thomas Dixon Savill, M.D., Lond. Physician to the West End Hospital for Diseases of the Nervous System; Physician to St. John's Hospital for Diseases of the Skin, London; formerly Medical Superintendent of the Paddington Infirmary, Medical Officer of the Paddington Workhouse, Assistant Physician and Pathologist to the West London Hospital, Post-Graduate Lecturer to the London Post-Graduate Association, Examiner in Medicine and Clinical Medicine in the University of Glasgow, Medical Officer to the Royal Commission on Vaccination. Second Edition, Revised by the Author, assisted by Frederick S. Langmead, M.D., London. Casualty Physician to St. Mary's Hospital; Assistant Physician to the Seaman's Hospital; Physician to Out-Patients at the Paddington Green Children's Hospital, and Agnes F. Savill, M.A. St. And., M.D. Glas., Assistant Physician to the St. John's Hospital for Diseases of the Skin. New York: Longmans, Green & Co.; London: Edward Arnold, 1910.

The second edition appears in one large volume which replaces the two smaller ones of the original issue. The main system of its predecessor has, however, been followed and that has been its chief claim to originality. Instead of working backwards the author begins from the bedside symptoms and then works up the differentiations which will afford a diagnosis. That his method has been accepted and appreciated is proven by the rapid exhaustion of the first edition and the production of its successor. For a reference book on diagnosis we know of none which would serve to help the puzzled practitioner out of his difficulties in a better or more thorough manner. The author's large experience at the Paddington Infirmary has given him a distinctly broad view of his subject, has served to make his knowledge practical and personal and the reader unconsciously accepts his views as rational and honest. He considers the methods of history-taking, the fancies, attitudes, etc., assumed in disease, the circulatory, respiratory, and abdominal diseases, a short chapter on gynecology, pyrexia, debility, pallor, emaciation, the skin, and nervous system. The chapters on the nervous system and on the skin are particularly useful and render these diseases into terms which are intelligible to a student or general internist. The author has kept apace with the times in his literature references and has evidently picked wisely from what has been offered.

It is with regret that we have to note the death of the author of this volume within a few months of its appearance. He has left behind him, however, the beginning of a new system of teaching medicine which will probably be followed by many.

A Synopsis of Surgery. By Ernest W. Hey Groves, M.S., M.D., B.Ss. (London.), F.R.C.S. (Eng.); Assistant Surgeon to the Bristol General Hospital; Surgeon to the Cosham Hospital; Senior Demonstrator of Anatomy at the Bristol University. Second Edition, Revised and Illustrated. New York: William Wood and Company, 1910.

In this new edition the author has thoroughly revised the book and brought it up to date. New chapters have been added on asepsis and antisepsis, shock, anesthesia, and diseases of the colon. The chapters on cranial surgery have been rewritten and provided with an illustration of cranial topography; a section is added dealing with surgical affections of the spleen; and the final chapter, or surface markings, is now fully illustrated, thereby adding much to its value. These additions amount to about one hundred pages. Properly used (that is, in conjunction with some standard text-book) this volume cannot fail to be of the very greatest assistance to students; the author has produced an admirable epitome, well arranged, of all the salient facts of surgery.

Transactions of the American Association of Genito-urinary Surgeons. Vols. III and IV. New York: Published for the Society by the Grafton Press, 1908 and 1909.

These two volumes contain papers read at the meetings of the Society, held on May 1 and 2, 1908, and on May 31 and June 1, 1909. The titles comprise many subjects of interest to the specialist in genitourinary diseases. Among the papers the following may be named to represent the contents of the volumes: Common Errors in the Treatment of the Urethra and Bladder, by Dr. James Pedersen; Contribution to the Surgery of the Prostate, by Dr. Samuel Alexander; Observations with the Rogers-Torrey Serum, by Dr. George K. Livinburne; Radical Operation for Tuberculosis of the Male Genital Organs, by Dr. George S. Whiteside; Diagnosis and Treatment of Vesical Tumors, by Dr. Hugh Young. Many articles are fully illustrated with photographs and line drawings.

Manual of Operative Surgery. By John Fairbairn Binnie, A.M., C.M. (Aberdeen), Professor of Surgery, Kansas State University, Kansas City; Fellow of the American Surgical Association; Membre de la Société Internationale de Chirurgie. Vol. II. Vascular System, Bones and Joints, Amputations. Fourth Edition. Revised and enlarged, with 550 illustrations. Philadelphia: P. Blakiston's Son and Company, 1910.

The four editions of this book since its first appearance in a single volume in 1905 attest its popularity. The popularity is deserved. It is an excellent and very practical book, and is the more admirable that though brief it does not lack in clearness. The great fault of most authors who attempt this task of condensation is that they sacrifice succinctness. Five methods of resection of the hip are given so that they can be understood, and the author does not neglect to say which he prefers. On page 438 a statement is made that seems characteristic: "If the surgeon and his assistants use their brains as well as their hands, it is easy to control hemorrhage in the course of the operation" (amputation at the shoulder joint). The chapter on congenital dislocation of the hip by Dr. Gwilym G. Davis is good, though the wisdom of devoting so much space to the various aspects of this deformity in a work like this may be questioned, as the author intimates in his preface. Mr. Robert Jones of Liverpool assisted in the writing of the chapter on club-foot, which is well done. One might criticise the author for his fondness for "swabbing cavities" with carbolic acid, Harrington's solution, etc., and might wonder how the operator is to distinguish diseased granulation tissue on the inside of the involucrum after acute osteomyelitis. These velvety granulations were much better left. The few small faults that one can pick out seem insignificant, however, in contemplating the book as a whole.

Nutrition and Dietetics. A Manual for Students of Medicine, for Trained Nurses, and for Dietitians in Hospitals and Other Institutions. By Winfield S. Hall, Ph.D., M.D., Professor of Physiology, Northwestern University Medical School; Lecturer on Physiology and Dietetics in Mercy Hospital and Wesley Hospital, Chicago. New York and London: D. Appleton & Company, 1910.

In this volume we have the results of a decade of teaching, making it a comprehensive working text-book. Its subject matter, as the writer tells us, represents practically his course for undergraduates in medicine, and for nurses. The material is concisely presented although it satisfactorily covers the field of nutrition and dietetics, meeting the needs of the general practitioner. The most recent researches on animal nutrition have been considered. The text is divided into four general parts: Foods; The Use of Foods in the Body; Diet in Health; Diet in Disease. In the first part are considered the chemical composition of the body, the needs of the body in growth and repair, and the needs of the working body. Then follow the subjects, natural foods for young plants, birds, and mammals, and the characteristics of these foods. The sections on classification and preparation of foods afford interesting reference material. After the section on digestion, absorption, assimilation, and waste products, follow those dealing with diets appropriate to various classes of people in health. The last part of this interesting book is devoted to the consideration of diet, in various disorders and diseases. In the appendix are given a classification of diets, recipes and sections on experimental chemistry in relation to food stuffs, foods, and digestion. This helpful volume supplies a demand that has not before been completely met. An excellent index adds greatly to its usefulness.

La Fonction du Sommeil. Physiologie, Psychologie, Pathologie. Par le Dr. Albert Salmon (de Florence). Paris: Vigot Frères, 1910.

Readers of French will find this an extremely interesting book. Sleep being a physiological phenomenon which occupies so much of our existence, is certainly worthy of serious study. The author presents some original ideas respecting the mechanism of sleep and the role played by the hypophysis and certain secretory glands in the production of sleep, and describes various disorders which disturb its function.

Initialerscheinungen der zerebralen Arteriosklerose und kritische Erörterung ihrer Pathogenese, Von A. Pick. Halle a. S.: Carl Marhold, 1909.

An interesting and suggestive contribution to a very important subject, by the well-known psychiatrist and neurologist, Professor Pick. It is brief, only 32 pages, and worthy of general reading.

Die Diagnose und Therapie des Kopfschmerzes. Von Dr. Med. Franz Windscheid, a. o. Professor a. d. Universität Leipzig. Zweite, völlig umgearbeitete Auflage. Halle a. S.: Carl Marhold, 1909.

This is a second and revised edition of a small brochure of only 68 pages, on headache, preaching throughout the gospel of careful histories and thorough examinations of patients for correct etiology and treatment of a most common symptom.

An Index of Symptoms; with Diagnostic Methods. By Ralph Winnington Leftwich, M. D., Late Assistant Physician to the East London Children's Hospital, Author of Syphonage in the Large Intestine. Fourth Edition. New York: William Wood & Company, 1910.

In this new edition a large number of signs and symptoms have been added, and the space devoted to diagnostic methods has been increased; at the same time the book is smaller in size than before. The introductory sections on art of diagnosis, classification of patients, and fallacies are of unusual value, and will be appreciated by many practitioners as well as by students. The work is complete, compact, and of undoubted value. A good index, coupled with judicious arrangement of type, headings, and indented margins, enables the reader to find any part of its contents without loss of time.

Tropical Medicine and Hygiene. By C. W. Daniels, M.B.Cantab., M.R.C.P.Lond., Director of the London School of Tropical Medicine; and E. Wilkinson, F.R.C.S., Eng., Major I.M.S. In three parts, with colored and other illustrations. Part I., "Diseases due to Protozoa." New York: William Wood & Company, 1909.

The scope of this book is fully set forth in the preface, where it is stated that medical men in the tropics should be practical sanitarians as well as clinicians. With this purpose in view, the present volume gives special attention to etiology and prophylaxis. The diseases are grouped according to their known or probable causation; the present instalment deals with diseases due to protozoa; in the next part, those due to the higher forms of life will be considered; and the third part will be devoted to bacterial diseases, to the effects of certain animal and vegetable poisons, and to diseases whose etiology is imperfectly understood. The present volume treats of Malaria, blackwater fever, piroplasmosis, yellow fever, human trypanosomiasis, kala azar, oriental sore, relapsing fever, tick fever, diseases due to spirochætæ in the tissues, syphilis, yaws, granuloma of the pudenda, and intestinal diseases due to protozoa. As an adjunct to books on Practice, the present volume has a distinct value. It is concise, practical, and accurate; and from a medical standpoint is all that can be desired.

Simon the Jester. By William J. Locke. New York: John Lane Company, 1910.

This book is replete with all the gentle fantastic charm that we have learned to look for from its author's pen, a charm compounded of many elements, among which may be found a kindly humor, the lambent play of a not too abstruse philosophy of men and manners, a comfortable ending, and last but not least, as it is one of Mr. Locke's most agreeable specialties—one or two uncommonly nice women. We are beginning to depend quite a little upon his power of differentiation with his womenkind, and we approve highly of the charming heroine of Simon the Jester. We trust that Mr. Locke may be spared to give us many repetitions of his triumphs.

The Surgery and Pathology of the Thyroid and Parathyroid Glands. By Albert J. Ochsner, A.M., M.D., LL.D., Professor of Surgery in the Medical Department of the University of Illinois, Chief Surgeon to Augustana Hospital and St. Mary's Hospital, Chicago, and Ralph L. Thompson, A.M., M.D., Professor of Pathology in the St. Louis University School of Medicine, St. Louis. With 57 Illustrations in the Text and 40 Full-Page Plates, 4 of the Plates Being in Colors. St. Louis: C. V. Mosby Company, 1910.

This volume is a work on a great and timely subject. It is divided into two parts, the first, "The Thyroid Gland," by Dr. Ochsner, except the chapter on its pathology, of which Dr. Thompson is the author, as also of the second part, "The Parathyroid Glandules." It is largely a treatment of the subject from the experience of the authors, but some space is given to history and to the work of others, especially of Dr. Louis B. Wilson on Pathology, whose excellent studies on classification and illustrations of cases (published elsewhere before) are given full credit. Among the points emphasized are: Diagnosis of exophthalmic goiter from simple goiter; importance of the parathyroid glandules in anatomy, physiology, and operative treatment; the recognition of reversion of a hyperplastic to a colloid goiter. As a contribution to the citation of facts on thyroid disease it is useful, and the plates illustrating steps in operating are helpful, even if too diagrammatic. As a specimen of medical book-making it is faulty, having glaring errors in proofreading, mistakes in punctuation and phraseology too common to be pardonable. It is needlessly bulky and gives one the impression that the attempt was to hurry the work through and to spread the dimensions of the book. We had hoped, too, that literary medicine had heard the last of "operating" a case instead of "operating on" it. With these qualifications the work is to be commended.

The Insanity Law of the State of New York. A Compilation of Statutes Relating to the Insane and to Institutions for Their Care and Treatment; to Which Are Appended the Official Orders and Regulations of the State Commission in Lunacy. By Frank P. Hoffman. Troy: Henry Stowell & Son, 1910.

The insanity laws were consolidated recently (1908) and this publication contains all the changes made at that time by the Legislature, and other matter of general interest respecting the insane in New York State.

The Serum Diagnosis of Syphilis and the Butyric Acid Test for Syphilis. By Hideyo Noguchi, M.D., M.Sc., Associate Member of the Rockefeller Institute for Medical Research. New York, Philadelphia, and London: J. B. Lippincott Company, 1910.

There is probably no man in America who has devoted more time to the study of hemolysis and its relation to syphilis and whose name is better known for his discoveries in this line than the author of this book. Not only has he made a deep study of the Wassermann reaction as described by the original discoverers, but he has by his own work so modified the older method that it is not only rendered much more simple a procedure than formerly, but is by many considered to be more reliable as well. From the pen of a man with Dr. Noguchi's reputation, a textbook cannot fail to attract interest. The present book is intended to be practical rather than academic. It is for the student and practitioner, not for the expert. Beginning with a few chapters upon the theory of hemolysis and complement fixation, written in a manner which makes this most complicated subject comparatively simple and intelligible, the author then goes into detail as to the technique of both the original Wassermann reaction and of his own modification thereof, describing with care and clarity the methods of preparing the solutions required, the apparatus needed and the technique of the actual making of the test. Chapter XI discusses the diagnostic value of the reaction. Chapter XII is a digression, but a most useful one, in taking up the Noguchi butyric acid test for syphilis and the parasyphilitic diseases. A complete bibliography is given for those who wish more than the practical use of the test, and following this is a glossary, a feature of the book of inestimable value to the student, who at first becomes hopelessly confused by the variety of terms used by different workers in the subject to designate the same thing. The book is eminently practical from cover to cover and should go far to make the serum diagnosis of syphilis a possibility even among those who have not the advantage of being near the great medical centers.

The Dietetic Treatment of Diabetes. By B. D. Basu, Major, I. M. S. (Retired). Second edition. Revised and Enlarged. Published by the Panini Office, Bhuvaneshvari Ashram Allahabad, 1909.

In this little volume of fifty pages the treatment of diabetes is outlined as the writer has found it appropriate in managing Indian patients, who are mostly vegetarians and teetotallers. Great stress is laid on the restriction or total interdiction of meat, alcohol, tea, coffee, and cocoa. The preparation and administration of many foods used only in India are discussed and the author emphasizes the statement that practice in India proves that diabetics who are vegetarians live longer than those who are meat eaters.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-fifth Annual Meeting, Held in Washington, D. C., May 3, 4, and 5, 1910.

THE PRESIDENT, DR. EDWARD P. DAVIS, PHILADELPHIA, IN THE CHAIR.

(*Concluded from page* 84.)

Extrauterine Pregnancy of Eleven Months.—DR. E. C. DUDLEY of Chicago said that this was the product of ectopic pregnancy removed July 20, 1909, two months after term. The mass was posterior and to the left of the uterus. The incision was made in the median line. The tumor was almost universally fixed by adhesions or by continuity of development. The adhesions were intestinal, uterine, parietal, omental, and they existed between the mass and all the adjacent structures, especially to the anterior abdominal wall and the sigmoid flexure. The mass, about eleven inches in diameter, was carefully separated from its adhesions and shelled out unruptured. The resulting raw surfaces were equal approximately to a surface not less than twelve inches square. An incision was made back of the uterus into the posterior vaginal fornix, and through this incision a continuous gauze drain was introduced from above downward into the vagina. The upper part of this drain consisted of gauze packing sufficient to fill the field of operation and to prevent oozing. This packing was then covered in by stitching together of the peritoneal surface above it in such a way as to cut off completely the field of operation from the remaining portion of the abdominal cavity, and to cover all with normal peritoneum. This suturing across the pelvis from side to side involved extensively intestinal structures, and especially the sigmoid flexure, which was stitched to omental, parietal, bladder, and other visceral peritoneum, wherever possible to bring the parts together, in order to quarantine the field of operation from the general peritoneum. The abdominal wound was closed without drain and healed promptly. A slight fecal fistula subsequently discharged through the vagina, but closed spontaneously in a few days. Such very extensive enucleation of so large a mass, due to ectopic pregnancy, ordinarily would not be undertaken. The fact that success followed this operation did not necessarily influence the author in recommending the procedure as a routine in similar cases. He reported this method with the suggestion that it might be considered more surgical than the conventional operation of incision and drainage, but, although more surgical, it perhaps might with subsequent experience prove to be more dangerous.

DR. EDWIN B. CRAGIN of New York had operated on four cases of ectopic gestation at full term. Two of the women were delivered of living children at the operation. In one of the four cases he was able to ligate the vessels supplying it and to enucleate the sac, but was obliged to take the uterus with it. All the patients recovered, but in only one case was he able to follow anything like the procedure of complete enucleation.

DR. E. E. MONTGOMERY of Philadelphia said that some fifteen years ago he operated upon a woman who was fifteen months pregnant. The uterus was in front of the sac. After opening the abdomen it was found that the small intestines were so intimately related to the sac that it was impossible to attempt its removal. The fetus was removed, and a communication made between the sac and the abdominal wall. The patient recovered

DR. HERMAN J. BOLDT of New York had had four cases of ectopic gestation at or near term, and in only one was it possible to remove the sac without rupture. He lost one of the four cases.

DR. A. LAPTHORN SMITH of Montreal had had two cases of tubal pregnancy at term. One of the women refused operation and was alive. In the other he removed the child, and when he attempted to enucleate the sac the hemorrhage was so profuse that he stopped and closed her up. The woman died in eight days from exhaustion.

DR. E. W. CUSHING of Boston had one of these cases many years ago, in which he waited until the child died. It seemed a safer thing to wait about a month, which he did, and then opened the abdomen. The sac was thin. The child was found loose in the abdominal cavity, was removed, and the woman recovered.

DR. O. B. MILLER of Washington D. C. had a case of ectopic gestation, about five years ago, on which he operated, delivering a living child at term. The whole sac with placenta was removed, and the woman recovered. The child died of hemorrhage following ligation of the cord by the nurse, to whom the baby was turned over at the time of the operation.

DR. JOSEPH TABOR JOHNSON of Washington D. C recalled a case of ectopic gestation which he had about ten years ago. The woman was supposed by those who saw her before he did to be twelve months pregnant. The nature of the case was clearly undersood, and at the operation doubt was expressed as to whether she was pregnant or not, but there was a large tumor on the side of the uterus, which was enucleated without breaking the sac. On opening the sac it was found to contain a full-grown fetus, weighing nine pounds. The abdomen was closed without drainage. The patient recovered.

Report on Vaccine Therapy in Gynecology and Obstetrics.—Drs. J. WHITRIDGE WILLIAMS of Baltimore, EDWIN B. CRAGIN of New York, and FRANKLIN S. NEWELL of Boston comprised the committee that made this report. The evidence at present available seemed to justify the following tentative conclusions concerning the value of vaccine therapy in gynecology and obstetrics: "1. Opsonins undoubtedly play a part in the production of active immunity. On the other hand, the determination of the opsonic index is technically very difficult, and is subject to such variations that it is not available as a diagnostic or prognostic guide, and even among trained bacteriologists there is considerable skepticism as to its practical value. 2. Immunization by means of vaccines is a well-established prophylactic measure against certain infectious disease, notably typhoid, cholera, plague, and dysentery. Vaccine therapy is undoubtedly a valuable remedial agent in local infections, due to the tubercle bacillus or staphylococcus, less so in local infections, due to other pathogenic bacteria, while there is considerable doubt as to its efficiency in acute general infections. 3. In chronic gonorrheal arthritis and urethritis it is a valuable adjunct to other treatment and occasionally may lead to cure alone. It appears to be useless in the acute infections, while it is more efficient in the treatment of the vulvovaginitis of children than any other means, but even here it does not always result in cure. 4. In infections of the urinary tract, especially those due to the colon bacillus, it sometimes results in symptomatic cure, but rarely relieves the bacteriuria. The scanty reports concerning the pyelitis and the pyelonephritis of pregnancy indicate that vaccine therapy is no more efficient than the usual treatment by rest in bed and the administration of salol or urotropin, as in neither does the bacteriuria disappear until after the termination of pregnancy. 5. In certain cases of endometritis it appeared to reinforce the curative influence of curettage. The reports concerning its use in pelvic inflammatory diseases were too scanty to justify conclusions, but it would seem that it might be of value only in chronic post-operative cases with sluggish fistula formation. 6. As the ordinary localized puerperal infec-

tions, irrespective of the nature of the offending bacteria, tend to spontaneous cure, the field for vaccine therapy is practically limited to acute general infections, whereas they unfortunately appear to be of little value, and the most that can be said from the reports thus far available is that their employment does no harm.

The Use of Vaccines in Septic and Inflammatory Conditions.—Dr. E. W. Cushing of Boston said that vaccines, or killed cultures, acted only by increasing the resistance of the patient. The opsonic index practically was not of much use in acute conditions. Autogenous vaccines were preferable to stock vaccines, except in certain cases of staphylococcus infection. The best results were obtained in the following order: Infection from colon bacillus, pneumococcus, staphylococcus. The results were not satisfactory with streptococcus in rapid virulent infections. In chronic infections and in cases of little virulence streptococcus vaccines gave satisfactory results, especially in moderate puerperal cases. Vaccines were not successful in acute gonorrheal infections, but were of much service in gonorrheal arthritis. Vaccines were useful in the following conditions: Puerperal infections, abortions, infections of bladder and kidneys, appendicitis, abdominal operations, postoperative pneumonia, and abdominal fistula.

The Surgical Treatment of Puerperal Septic Infection.—Dr. E. E. Montgomery of Philadelphia said the most effective safeguard against the baneful influence of sepsis was the practice of such measures during the parturition and puerperium as would lessen the opportunities for its production, but such measures did not properly enter into this discussion, for their careful practice would obviate the necessity for any consideration of surgical measures. The suspicion of sepsis confirmed, the course of the surgeon must very often be a tentative one, and largely dependent on the period at which the patient came under observation. Rarely after the diagnosis was definitely determined was it worth while to resort to the use of the curette. The infective germs very rapidly passed beyond the superficial structures, so that the procedure of curetting was ineffective to limit the progress. The entire removal of the uterus would not always be adequate, so operative procedure should be delayed until it was evident there existed such a localization as shall make operation effectual in arresting further baneful progress. The results of serum therapy were not always so satisfactory, as not infrequently its employment was begun too late, or the virulence of the infection was so marked that the best result to be obtained would be a local manifestation of the poison which would still require resort to the knife for the safety of the patient. A case was cited in point. Extensive peritoneal exudate entirely surrounding the uterus and fixing it and the appendages might be entirely absorbed and the patient restored with functioning organs by rest, regulation of the diet, moderate depletion, and the judicious use of improvised carbonic acid baths. The constant course of the surgeon should be one of watchfulness, utilizing every force at his command to conserve the functions of the patient, yet to proceed unhesitatingly to the most radical measures when such seemed necessary to preserve life.

When Shall We Operate in Puerperal Sepsis?—Dr. John Osborn Polak of Brooklyn, New York, read a paper on this subject, which was based on a study of two hundred consecutive cases. He drew the following conclusions: 1. That each case of post-partum or post-abortal infection must be studied individually, and an accurate diagnosis must be made on the clinical, bacteriological, and blood findings, before any treatment was instituted. 2. Nature was competent in the majority of instances to localize and circumscribe the infection. 3. Curettage, douches, and examinations during the acute stage broke down barriers and opened avenues for the further dissemination of sepsis to the myometrium, parametrium, and adjacent tissues, and that the danger from curettage increased with each month of pregnancy. 4. Enormous pelvic and abdominal exudates may disappear without operation, and that in time enlarged ovaries, tubes, etc., might assume their proper size and function, and further, that as long as the patients' general condition improved, no surgery was advisable. 5. All operations were attended with less risk after the acute stage of the infection had subsided, and an exact diagnosis was more easily made at this time. 6. After the uterus was thoroughly emptied, the pelvis should be left absolutely alone, and efforts should be made to support the patient and increase her natural blood resistance. 7. Extraperitoneal drainage of local foci should be elected when possible, either by incision just above Poupart's ligament, or by posterior vaginal section, and, when this was impossible, because of an inability to determine the exact anatomical relations of the local foci, an exploratory laparotomy was justifiable in order to make an exact diagnosis and determine upon the safest route for drainage. 9. Operative interference in the acute stage of sepsis was only indicated in general purulent peritonitis, post-abortal pelvic peritonitis, infected tumors in or near the genital tract, and uterine rupture, when the rupture had occurred in the course of labor, and had been handled outside of a well-managed maternity, and finally that thrombophlebitis was a conservative process on the part of nature to limit the infection, and that any form of pelvic manipulation only tended to break down and separate parts of these thrombi, extending the infection to the more remote parts, thus jeopardizing the patient's life.

The Surgical Treatment of Puerperal Septic Infection.—Dr. Hiram N. Vineberg of New York said that surgical intervention, if curettage be not included, came into consideration in only a small percentage of cases of puerperal sepsis. The selection of these was difficult for want of reliable guides, bacteriological or clinical, as to the course and prognosis of a given case. Hysterectomy was indicated (a) when the uterus contained putrid placental remains that could not be removed with the finger or curette; (b) when the uterus contained a sloughing fibroid; (c) when the uterus was studded with abscesses; (d) when the uterus had been subjected to severe traumatism and gave evidence of infection. The status of ligation of the pelvic veins in puerperal septic thrombophlebitis was still *sub judice*. The results thus far warranted a further trial with the procedure. In acute puerperal septic peritonitis good results had been obtained by the Germans with multiple incisions and drainage. Perimetric and parametric abscesses should be approached without entering the general peritoneal cavity. In unilateral pyosalpinx or ovarian abscess, the usual median laparotomy incision should be avoided, and, instead of it, one should be made over Poupart's ligament or at the outer ridge of the rectus, so as to avoid entering the general peritoneal cavity. Although the author was an advocate of major surgical intervention in suitable cases, he had had occasion during the past seven years to extirpate the uterus in only six cases. From this it could be inferred that it was only very rarely that major surgical intervention was indicated in acute puerperal septic infection. The vast majority of the cases got well under appropriate general treatment and such minor surgery as the exigencies of the given case might call for.

Is Pubiotomy a Justifiable Operation?—Dr. J. Whitridge Williams of Baltimore read a second communication based upon a series of twenty-five successful cases, and drew the following conclusions: 1. In twenty-five pubiotomies performed at the Johns Hopkins Hospital there were no maternal, but three fetal deaths, only one of which was attributable to the operation. 2. All patients were delivered by forceps or version immediately after pubiotomy.

There were no injuries to the bladder. There were six perineal and five deep communicating vaginal tears, notwithstanding the fact that twelve of the patients were primiparæ. 3. The relative infrequency of injury to the soft parts was attributed to restricting the operation to suitable grades of pelvic contraction, and to the employment of Doederlein's technic, but particularly to extensive manual dilatation of the vagina and perineum prior to operating. The occurrence of such injuries might be still further decreased by making horizontal instead of upward traction when delivering the head through the vulva. 4. The after-treatment was not so onerous as was generally stated, and most of the patients suffered but little. Immobilization of the pelvis was not necessary, a four-inch adhesive strip around the trochanters being sufficient. The patients usually moved spontaneously in bed between the second and fourth days; they got up between the fifteenth and twentieth, and were discharged on the thirtieth day with satisfactory locomotion. Healing generally occurred by fibrous union, so that there was definite motility between the ends of the bone in at least two-thirds of the cases. 5. The maternal mortality should not exceed two per cent. provided the operation was performed by competent operators upon uninfected women, who had not been exhausted by previous attempts at delivery. 6. It was indicated in contracted pelves where the conjugata vera exceeded seven centimeters, and after a test of several hours in the second stage of labor has shown that the disproportion could not be overcome, as well as in certain funnel-shaped pelves. 7. Prophylactic placing of the saw was indicated prior to breech extractions or versions from transverse presentations when it appeared problematical whether the head could pass through the pelvis, and the bones sawed through immediately after discovering the disproportion. 8. In multiparæ with a history of repeated difficult labors, or in primiparæ presenting excessive disproportion, pubiotomy was inferior to cesarean section performed at the end of pregnancy or at the onset of labor; otherwise it did not enter into competition with it, as the former was the operation of choice in border-line pelves after the patient had been subjected to the test of labor, and at that time it was many times less dangeraus than the classical cesarean section. 9. In uninfected women it should replace high forceps, prophylactic version, induction of premature labor, and craniotomy upon the livng child. In how far it might compete with suprasymphyseal cesarean section must be shown by future observations. 10. It should not be employed in infected patients or after failure to deliver by other means. It should be regarded as a primary operation whose dangers were infection, deep tears, and hemorrhage. 11. Where the separation between the cut ends of the bone did not exceed four to five centimeters, the patients recovered perfectly and were able to walk and work as well as previously. 12. In view of the fact that the bone section usually healed by fibrous union, a certain degree of permanent enlargement of the pelvis might follow, particularly in the transverse diameter of the outlet, and less so in the conjugata vera. Under the influence of the hyperemia incident to a subsequent pregnancy, this might occasionally become markedly exaggerated and be sufficient to permit spontaneous labor. Should this not occur, a second pubiotomy might be performed, while cesarean section should be limited to those cases in which the pelvic contraction was marked and the child large.

What Are the End Results of Surgery or Surgical Operations for the Relief of Neurasthenic Conditions Associated with the Various Visceral Ptoses? To What Extent Do They Improve the Neurasthenic State Itself?—The American Gynecological Society and the American Surgical Association devoted one entire joint session to the discussion of this subject.

Dr. Edward Reynolds of Boston, in opening the discussion, took up the etiology of the ptoses and their relation to neurasthenia. He said that satisfactory end results depended upon a successful initial study of the causation of the individual ptosis, and of its consequent relation to the neurasthenia. Technique was a subordinate matter. Ptosis was never a primary affection, but was always secondary to some other condition. The causes of ptosis were (a) local anatomical or developmental anomalies, and (b) general systemic mechanical conditions. The local causes of ptosis of pelvic viscera were inflammatory lesions, trauma, high rectovaginal septum, persistent ileolumbar ligament, and anteflexion of the cervix. Operations should be adapted to these causes. The general predisposing causes of all ptoses were (1) general muscular relaxation, and (2) static abnormalities, such as a round-shouldered, hollow-backed position, pendulous abdomen, the over-feminine figure, and the habitual use of bad corsets. All these static variations were characterized by a forward displacement of the center of gravity. The mechanics of adjustment of posture were comprised in the use of therapeutic shoes and corsets. Mechanical therapeutics was always necessary in static cases. Ptosis was sometimes the result of neurasthenia, sometimes its cause. The main guide was the relative chronological sequence of local and general symptoms. It was important to avoid operation in neurasthenics unless complete relief of the local symptoms could be expected. The importance of subsequent care was emphasized.

Dr. Joseph A. Blake of New York said that patients suffering from visceral ptosis and neurasthenia should be divided into two classes, first, those in which ptosis of the organ or organs contributed to the neurasthenic state simply by the effect produced on the organs themselves. In this category we had displacements of the kidney, uterus, colon, stomach, etc. The results of operations upon this class were dependent upon the degree in which the condition affected the neurasthenic state. In the second class of cases a vicious circle was established, and ptosis increased the neurasthenic state if it was not the underlying cause. Operations undertaken upon patients of this class must have in view the relief of the autointoxication, otherwise they would only be productive of harm. Partial or total exclusion of the colon was a rational procedure in certain cases and good results might be expected, but the greatest care should be exercised in the selection of cases for applying this operation.

Dr. John G. Clark of Philadelphia said that we had a defective individual to deal with from the start, and as the result of this defect we could not hope for the same surgical results as we would get from operating on patients with acute disease. The individual, perhaps, had had autointoxication from the beginning, or was imperfectly developed from the start, and, therefore, a bad surgical subject for immediate or ultimate results, and it was particularly in this class of cases where surgeons should make haste slowly. In the last five or ten years he had tried various types of suspension operations in cases of visceral ptoses, such as the Coffey or the Beyea type of operation, and had not had more than 75 per cent. of functional relief after following these cases carefully. In those cases in which there was a structural defect, as was shown by obstructive and retention symptoms, one did not hope to get more than 50 per cent. of functional relief.

Dr. Maurice H. Richardson of Boston said he approached the treatment of the neurasthenic for whatever cause, whether a definite, unmistakable pathological lesion, or a ptosis, or a slight lesion, like a displacement of the kidney, with the utmost discouragement. One of his recent cases was a woman whose abdomen was covered with scars from repeated operations that had been performed without relief, her last state being worse than the first. Finally, it was found that this woman's gall-bladder was

full of gallstones, which were removed, followed by relief. As to enteroptosis and operations for large dilatations of the intestine, he could recall examples of cases in which he was driven to operation after these patients had gone to the neurologist, the gynecologist, the general surgeon, and had been treated by them without relief, but with the same general results of discouragement. In one instance, eight or ten years ago, he resected the large intestine two or three times with the hope of affording relief, but the patient was in the same neurasthenic condition as in the first place. In addition to the operation on the intestine, she had developed a large ovarian cyst, which was removed. Before operating on these cases, he thought, first, we should be sure that there was a lesion; second, that it was the chief cause of the neurasthenia; third, we should see if it could not be cured without operation, but if operation was to be done, we should see to it that it did not subject the patient to too great a danger. He believed neurasthenia was more of a disease than we gave it credit for, that it was some central, organic, or nervous condition on which operative surgery would have very little or no effect, ultimately.

Dr. Richard R. Smith of Grand Rapids, Mich., confined his remarks to a general consideration of the etiological factors to be thought of in connection with visceral prolapse, and accompanying neurasthenia in women who presented themselves to the gynecologist for the relief of symptoms.

Dr. Lewis S. McMurtry of Louisville said that very often, after difficult manipulations in the abdomen, in the haste of operation, viscera were disposed in every possible irregular manner, and yet they corrected themselves in normal individuals, and they necessarily had no connection with neurasthenia, so that we must have a little more evidence than we had at present that visceral ptoses were the principal factors in the production of this condition of the nervous system and metabolism of the body known as neurasthenia, and he thought that the error in our procedures had been in assuming that these visceral ptoses were in all cases the cause of the neurasthenia. As to the clinical side, his experience was like that which had been related by other surgeons. Operative procedures for all these ptoses, whether of the pelvic organs, the kidney, or the alimentary tract, had been unsatisfactory. Neurasthenia occurred in both sexes in all stations and all conditions of life, among the rich and the poor, and its exact nature or its pathology was as yet unknown, and until it was more definitely known the results were going to be as they were reported to the profession at the present time. What was needed was a definite statement as to the origin or cause of this condition which was known as neurasthenia.

Dr. William M. Polk of New York stated that in patients who presented themselves with ptoses that had been described as belonging to the upper abdominal cavity, we had conditions that unquestionably caused us to balk, but here he was convinced that orthopedics furnished a most efficient aid, and the lines laid down by Dr. Reynolds and by Dr. Lovett of Boston would be the means of benefiting very many of the conditions at the present time for which surgery had been considered the only means of relief. But the psychoneurologist should not be forgotten in connection with these cases. There was no reason why gynecologists and surgeons should bear all the burden in these cases. He had long since come to the conclusion that there was a conspiracy on the part of the neurologist to land on the gynecologist and surgeon a class of cases which he knew full well would test every particle of his acumen, and here was a brilliant opportunity for the psychoneurologist to exploit himself to the fullest extent. When these neurasthenics came to the gynecologist or to the surgeon it should be said to them, first pass through the hands of a competent orthopedist; pass next through the hands of a conscientious self-doubting neurologist, but beware of the over-confident neurologist, and then the surgeon would say: "Madam, or Sir, as the case may be, as you have reached the end of all things, so far as medical investigation is concerned, I am now more than willing to commend all the resources of my refinement of the surgical art."

Dr. A. J. Ochsner of Chicago subscribed to the statements made by Dr. Blake in regard to the surgical care of this class of cases. He said there was no doubt that the condition of neurasthenia could be greatly exaggerated or possibly caused by the results of enteroptosis, particularly when these results produced obstruction either to the alimentary canal and interfered with nutrition and caused autointoxication, or when the condition gave rise to obstruction of the ureter, or caused an accumulation of mucus in the gall-bladder, and secondarily, caused gallstones. The relief, after an operation on such cases, even though the neurasthenia was possibly caused by this condition, must be in most cases exceedingly unsatisfactory, and due largely to two causes. First, we did not mechanically relieve the condition no matter how perfect the operation might be, except in a few instances, as in draining and suspending the gall-bladder in removing a hydronephrotic kidney. Dr. Reynolds' presentation was along the line of observations he had made which caused him to suggest prophylaxis rather than treatment in this way. Many years ago, in studying the treatment of hernia in children, he fould that hernias in children were cured spontaneously, provided conditions were secured in which there was absence of abnormal intraabdominal pressure and traction by placing these children in a position with the foot of the bed elevated at from 15 to 30 degrees. He found that in these children with pendulous bellies the recti muscles came together if they were shortened, that the oblique muscles were strengthened, and that the intestines instead of hanging at the bottom of the pelvis, would, after a few months' treatment, be in normal position. He found that this enteroptosis in children had resulted from improper feeding, from gaseous distention, and from other sources of abnormal intraabdominal pressure. In some of these cases the increased abdominal pressure was due to severe straining from constipation, and with the relief of this the enteroptosis in children was decreased to a very marked extent. He thought by overcoming the causes of enteroptosis in children, we would prevent its occurrence in many adults.

Dr. Howard A. Kelly of Baltimore restricted his remarks to the various types of nervous systems associated with movable kidney. Movable kidney was frequently found in neurasthenics. Movable kidney, associated with renal pain, might exist to such a marked extent as to bring on the neurasthenic state. The symptoms connected with movable kidney sufficient to justify operative procedure, were, as a rule, definite, and of a local mechanical nature. Psychotherapy was of little use as an adjuvant in treating neurasthenics and in relieving either local or general ptoses so long as a displacement of the kidney persisted. On the other hand, psychotherapy and other forms of treatment, which aimed at building up the patient's general condition, might seemingly effect a cure. In an analysis of 245 cases of nephroptosis, 78 or 31.4 per cent. had neurasthenia of varying degrees. Personally, the speaker never operated on neurasthenic patients without definite local symptoms.

Dr. Willis G. Macdonald of Albany said that not all patients who suffered from ptoses were neurasthenic. A very large proportion of them did not present symptoms. In a large number of these cases of neurasthenia associated with ptoses the responsible conditions were autointoxication from the intestinal tube and peripheral irri-

tations from movable organs. He divided patients suffering from neurasthenia and ptoses into two classes. In the first class there were those patients who traveled from rest cures to rest cures, from one climate to another, and who were pretty generally battle-scarred from their conflict with surgery. For this class surgery had no potency. There was no hope for relief from surgical intervention in such cases. On the other hand, there was a considerable group of cases in which the condition could be traced to an overloaded cecum and sigmoid—a constant filling of the intestinal tube, with a large, dilated myasthenic stomach lying upon the symphysis pubis. Operation would relieve successfully a large number of such patients, yet, unfortunately, clinical methods were not sufficient to determine always just which cases would be favorably influenced by surgical intervention and those which would not, and in making statements to physicians and friends of such patients we should, as a matter of common honesty, express some doubt as to the ultimate results in this particular class of cases.

Dr. John K. Mitchell of Philadelphia stated that the whole causation of neurasthenia was bound up in a kind of vicious circle where one symptom produced another until one positively could not disentangle the chain. What did we know about the normal relations of the abdominal organs? What did we know about the position in which the various organs in the belly ought to be in the ordinary upright posture which we maintain a large part of the time? How much mobility should such organs as the kidney and liver have? Apparently, from the manner in which the intestines were distributed in the belly, they were not placed there like articles on a shelf to be maintained in one position, but they possessed a certain amount of give and take. He saw very few neurasthenics in which the kidney did not have more or less play, and slightly movable kidneys sometimes gave worse symptoms and caused more trouble than those which were freely movable, and a floating kidney, unless it resulted in a twisting of the ureter and stoppage in that way, causing pain in the ureter and in other portions of that neighborhood, did not produce so much symptoms as a kidney that was only slightly movable, one in which it would be difficult to determine whether it was movable or not. Before operating on a neurasthenic patient the surgeon should have a definite idea as to whether a pathological condition existed or not, what he was going to do, and what he hoped to accomplish by the operation, otherwise the results from surgical intervention would be unsatisfactory.

Dr. William J. Mayo of Rochester, Minn., agreed with Dr. Clark that these patients were wrong from the beginning, and his own feeling was that but a small number of them should be treated surgically. For some years they had made a careful examination of all patients who presented themselves, no matter whether they had cancer of the breast or gallstones, or what not, and to their surprise they found that about 25 per cent. of the women had retroposition of the uterus. They did not find that retroposition of the uterus was more frequent in the latter decades of life. Even young girls who came to them, in whom pelvic examinations were made through the rectum, had retroversion of the uterus in about the same proportion of cases as those women who had reached the menopause. Again, they found 20 per cent. of the patients had movable kidney, and a very large majority of them did not have any symptoms of that condition. From a surgical standpoint, neurasthenics should be treated like the insane, in that no cognizance whatever should be taken of their general complaints, but if they had sufficient local pathology to warrant operation, they should be operated on, as surgeons had no right to deny this class of patients the relief that came from surgery. Doubtless, many of these patients could be benefited by the Emmanuel movement or by Christian Science, and many practitioners would gladly turn them over to the Christian Scientists if they were convinced that the Christian Scientists were really Christians, because, he said, it really took a Christian to handle them.

Closing remarks by Drs. Reynolds and Blake brought the joint session to a close.

Fibromyomata of the Uterus.—Dr. I. S. Stone of Washington, D. C., gave his views on the various practical points in connection with the general subject, such as the age of patients, the complications frequently encountered in performing hysterectomy, and the pathological changes found in the tumors themselves. He reported 160 abdominal hysterectomies, all of which had been performed in one of the hospitals with which he was connected. Thirty of the number were complete hysterectomies, but the ovaries were not always removed. He thought the operation at the present time was nearly as safe as ovariotomy so far as the saving of life went, but the morbidity was not as low as in the latter operation. The complications resulting from the degenerative changes in the tumor, the danger of sepsis from the proximity to the vagina, and the greater exposure of pelvic connective tissue in hysterectomy would always be considered more productive of mischief than the conditions which followed in the wake of ovariotomy. The author gave the question of mortality much attention and quoted from the reports of operations in various hospitals to show the marked improvement in results during the last decade. The average mortality was now about 4 per cent., but many operators had obtained a much lower rate.

Extensive Malformations and Malpositions of the Urogenital Organs.—Dr. Thomas S. Cullen of Baltimore gave the clinical history of a patient, aged seventeen, white, who came complaining that she had never had her menstrual periods. On examination he fould total absence of the vagina, but by rectal examination was able to detect a mass filling the right half of the pelvis. This mass he thought might be the uterus with retained menstrual flow. An incision was made between the bladder and rectum until the mass was reached. It was found to be hard. The abdomen was at once opened and filling the right half of the pelvis was a somewhat irregular mass. This on its inner aspect had a definite cleft which suggested the pelvis of a kidney. A hand was carried up into the right renal pocket, but no kidney was present at that point. Examination of the left side failed to reveal any left kidney. He was dealing with a right pelvic kidney. There was no uterus. Half of the right tube emerged from the inguinal canal. The remaining portion of the tube and the corresponding ovary lay in the inguinal canal. A small loop of round ligament was seen emerging from the inguinal canal. On the left side the tube and ovary could not be seen, but could be felt in the inguinal ring. A small portion of the round ligament was discernible. He briefly discussed the relative merits of Baldwin's operation, where a vagina was made from a portion of the intestinal tract, and Ferguson's operation where a new vagina was made by turning in skin flaps. Dr. Cullen demonstrated a specimen of adenocarcinoma of the Fallopian tube coming from a patient, forty-six years of age. The chief interest in this tube lay in its immense size. It formed a tumor 14 x 12 x 10 cm. Near the uterus the tube was normal in size. After it had passed out five centimeters, it was five centimeters in diameter, and its outer and occluded end was ten centimeters in diameter. The great distention of the outer end of the tube was in part due to an accompanying hydrosalpinx. The growth was limited almost entirely to the inner surface of the tube. It was of a distinct papillary variety. The left tube was also involved in the carcinomatous process. This was one of the largest carcinomas of the tube on record.

The Repair of Inaccessible Vesicovaginal Fistulæ Following Hysterectomy.—Dr. George Gray Ward of New York described the method he had adopted in two cases, with satisfactory results. The important steps which led to a successful result in the method he employed were: 1. The differentiation from a urethral fistula by distention of the bladder with an anilin solution. 2. The employment of deep paravaginal incisions as described by Schuchardt. 3. A longitudinal incision on the anterior vaginal wall from the urethra to the vaginal vault through the fistula and extending into the posterior vaginal wall, and a lateral incision extending the full width of the vaginal vault. 4. The thorough separation of the base of the bladder from the entire anterior vagina and vaginal vault, being careful to commence the dissection in the lower vagina where there was an absence of scar tissue to establish the line of cleavage. 5. Evisceration of the bladder into the vagina by means of a sound or similar instrument passed through the urethra. 6. The closure of the opening in the bladder separately from the vaginal incision.

The Influence of the Trendelenburg Position on the Quantity of Urine Excreted During Anesthesia.—Dr. J. Wesley Bovée of Washington, D. C., said that after having recently studied eight cases of ether anesthesia and eight of chloroform, he believed the results demonstrated that almost no urine was received in the bladder while the Trendelenburg position was being employed. If it could be concluded that the renal function was greatly lessened while the patient was in the Trendelenburg position, then the dangers of that position were at once appreciated. In renal inefficiency, cardiac and arterial lesions, it would seem the use of the Trendelenburg position would introduce a special element of danger, and this more marked when ether was used than when chloroform was employed as the anesthetic.

The Postoperative Treatment of Abdominal Section for Pelvic Disease.—Dr. Brooks H. Wells of New York said it was found that getting the patient out of bed early after operation encouraged her, lessened nausea, promoted an earlier return of appetite, increased peristalsis, made the use of the catheter seldom necessary, made the bowel movements easier, so that there was less necessity for purgatives, improved the respiration, lessened the tendency to pulmonary complications, prevented loss of muscle tone, and greatly facilitated a rapid convalescence. The only contraindications were (1) shock or general weakness, as expressed in a rapid and weak heart, so that one might fear cardiac failure from the upright position. (2) Cases where, with a long median incision there had been much tension, required in bringing together the fascial edges. (3) Cases that developed septic temperature or deep wound infections. Of the cases that formed the basis of the paper, over one hundred had been operated on through a transverse incision, and of these none had developed hernia. Two of the median incisions were known to have developed hernia, but neither patient was allowed out of bed early.

Report of the Committee of the American Gynecological Society on the Present Status of Obstetrical Education in Europe and America.—This committee, consisting of Drs. E. B. Cragin, J. E. Edgar, C. M. Green, E. P. Davis, J. W. Williams, J. C. Webster, and B. C. Hirst, chairman, recommended that the teaching of obstetrics should occupy at least two years of the medical course, and that those expecting to practise obstetrics should be urged to avail themselves of elective opportunities. That the number of labor cases personally attended by each undergraduate student should be at least six, under supervision and instruction. The committee recommended all the known methods of teaching this branch of instruction, namely, didactic lectures, clinical lectures, clinical conferences, ward classes and touch courses, hospital and out-patient instruction, manikin practice in operative obstetrics, and recitations. Of the first three methods, the committee recommended especially clinical lectures and conferences. It recommended that ample facilities be afforded to make antepartum examinations, including inspection, abdominal palpation, pelvimetry, fetometry, vaginal examinations, etc. The committee recommended that a two weeks' hospital residence should be required before the out-patient practice. It was recommended that as obstetrics at present included pregnancy and parturition, their complications and consequences and the complete recovery of the woman after labor, that obstetric instruction should include the medical and surgical treatment of these conditions. The tendency of obstetrics to become more surgical in practice and to require a surgical training was evidenced by the fact that in the medical schools of Europe, and in more than one-third of the first fourteen medical colleges of this country, the chairs of obstetrics and gynecology were combined under one head.

On motion, the report of the committee with recommendations was adopted.

Cesarean Section for Impassable Contraction Ring.—Dr. Robert L. Dickinson of Brooklyn, N. Y., said that apart from a consideration of contracted pelvis, or a relative disproportion beween the passage and passenger, or blockade by scars or tumors, section for impassable contraction ring was warranted when the following conditions were present: 1. Child living and not definitely enfeebled or endangered by the length of labor or by unskilled attempts at extraction. 2. The ring refusing to relax under morphia or complete anesthesia, or to yield to patient manual dilatation by a skilled obstetrician. 3. Mother in fair condition for a laparotomy and not infected. 4. Request by patient and husband that a somewhat increased risk to the mother be assumed for the sake of obtaining a living child in lieu of embryotomy. These indications were perfected if at a previous labor in expert hands this same condition of the contraction ring had caused the loss of a child not unduly large. This held good whether the ring was in advance of the head or about the neck. The association of a rigid ring with other reasons for section was frequently present. The following case seemed to be the first instance of deliberate section for the indication—rigid ring in advance of the head. Dr. Watts' cases appeared to be the earliest for neck constriction, and these three, the first classical cesarean sections for contraction ring blockade. A healthy woman of twenty-six was delivered at the thirty-second week with forceps. The contraction ring did not relax under chloroform and the death of the child was due to the amount of traction necessitated. Two years later, at the thirty-fifth week, she fell into labor in his care. A thumb-thick circle admitting two fingers lay just above the plane of the pelvic brim. Morphia did not help except to rest the patient. Attempts at dilatation under anesthesia failed. The ring retained its contraction after the emptying of the uterus. Both patients did well. The literature showed five cases, all hysterectomies, two after failure of embryotomy, only one, that of Sinnetamby, for transverse presentation being undertaken for the indication with a living child. The author carefully summarized the literature on the whole subject of the retraction ring since 1899, when it was fully covered in Cheron's book.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. Reuben Peterson of Ann Arbor, Mich.; *Vice-Presidents,* Drs. John F. Thompson of Portland, Me., and John C. Clark of Philadelphia; *Treasurer,* Dr. J. Wesley Bovée of Washington, D. C.; *Secretary,* Dr. Le Roy Broun of New York.

Atlantic City, N. J., was selected as the place for holding the next annual meeting.

THE AMERICAN THERAPEUTIC SOCIETY.

Eleventh Annual Meeting, Held at Washington, D. C., May 5, 6 and 7, 1910.

JAMES C. WILSON, M. D., OF PHILADELPHIA, PRESIDENT, IN THE CHAIR.

Thursday, May 5—First Day.

The address of welcome was made by Dr. HARVEY W. WILEY of Washington, D. C., and the response to it by Dr. ALEXANDER MCPHEDRAN of Toronto, Canada.

Address of the President.—Dr. JAMES C. WILSON took for his subject "The Progress of Therapeutics." In speaking of the universities which sprang up in almost every important city of Europe under the influence of the Renaissance, he said that the faculties of theology, arts, law, and medicine were gradually differentiated, and that medicine was prominent in every school. In some, as Salernum, medicine was long the sole department; a suggestive commentary upon modern university organization, in which sometimes all the faculties were found represented except that of medicine; or, again, with a medical department dragging on an unsatisfactory existence by reason of inadequate equipment and a discouraged and not altogether harmonious faculty. Having traced the history of medicine to later times, he said that with the development of pathological anatomy on the one hand and of clinical methods on the other, came that division of labor to which we owed the specialties, a concentration of energy which might be compared to intensive farming, and which had done more to secure accuracy in scientific observation in clinical work and precision in therapeutic measures than any other event in the history of medicine. Bacteriology, the youngest of the natural sciences, daughter of the genius of Pasteur and Koch, came into being, and thus at the beginning of the last third of the nineteenth century the study of causes found a sure foundation in the facts of science, and empiricism in therapeutics gave way to rationalism. Half a century had not yet elapsed, and the art of healing showed signs of being revolutionized. Many pathogenic bacteria were known to us by specific morphological, tinctorial and cultural characters, but the existence of others which had eluded the known methods of research might be inferred, as in the case of measles, for example, from the constancy of certain associated morbid phenomena. The blood serum, not long ago regarded as a simple solution of albumin and certain salts, was now known to possess properties in health and disease of the most subtile and occult characters and potentialities in regard to infection, immunity and therapeusis equally mysterious. The history of the advance of medicine would be but a series of disconnected episodes were it not that it taught us that here, as in other fields of human endeavor, knowledge ripens slowly and that failures are the stepping-stones to success. It taught us also that the control of effects can be compassed only through a knowledge of their causes. There were more than two thousand years of empiricism before reason came to her own in medicine. Jenner alone in all time before the era of bacteriology—our era—applied the knowledge of causes to preventive medicine and wrought the wonder of a rescued world. To-day we watched the effects of the antitoxin made possible by the work of Klebs and Loeffler, or those which follow the administration of Flexner's serum, and experienced the sensation of having witnessed a miracle. In modern times there had been less and less of indirection and a progressively increasing tendency toward practical results. Specialism and organization were complemental. Without the one the other could not exist, and the new medicine was the product of this union. A comprehensive survey of the work done by the members of the American Therapeutic Society individually and collectively discovered here also a well-defined tendency to specialism. Three main therapeutic trends had been differentiated: first, the Hippocratic medicine in which the forces of nature other than drugs played the most important rôle; second, the subject of psychotherapy and reeducation in the management of functional neuroses; and, third, the general study of therapeutics as comprising the empiric use of drugs on the one hand and the rational employment of causal remedies upon the other. Their work consisted in the application of the means to the end, and the time was now at hand for them to enter upon the latest phase of applied therapeutics, namely rational therapeutics based upon the latest results of the scientific study of the causes of disease, serum therapy, opotherapy and the use of bacterines. A convention for the ninth decennial revision of the U. S. Pharmacopœia was to be held in Washington in a few days, and in view of this fact it had seemed appropriate that a symposium upon matters concerning the Pharmacopœia should form part of the society at this meeting. Those who were to take part in it were men especially interested in the matter, most of them delegates to the convention and all qualified to speak with authority upon the subjects to be discussed, especially from the standpoint of the practitioner of medicine. It was the confident hope of the members of the society that this discussion would exert an important influence upon the transactions of the approaching convention.

The Treatment of Pneumonia.—Dr. ALEXANDER MCPHEDRAN of Toronto pointed out that the disease is a marked general infection, with a very marked local one in the lung, and that the lung infection has already occurred when the symptoms become well defined. This rendered the arrest of the disease a difficult matter. Death from pneumonia was usually due to cardiac failure, which, in turn, was caused by the depression of the circulatory center in the medulla from the toxic albuminoid of the pneumococcus. Cases of cardiac failure might be divided into two groups: (1) The asphyxial, in which there were signs of failure in the right heart, with cyanosis. The great majority of cases belonged to this group. (2) The syncopal, in which there was anemia of all parts, due probably to paresis and consequent dilatation of the splanchnic vessels. In this condition the heart, in common with other organs, suffered from anemia. Since virulent pneumococci were so frequently found in the mouth, it followed that there must be strong resisting power in the body-fluids in health to prevent their invasion of the blood stream. Of late years the disease had been regarded as greatly on the increase, and this was probably due to the prevalence of influenza. Samuel Nest had shown from the Registrar-General's Statistics that there is a remarkably close relationship between the prevalence of influenza and of pneumonia since the first epidemic of the former in 1889. From this we might infer that the first step in the prophylaxis of pneumonia was to maintain rest and good care until complete recovery from influenza and other depressing diseases. We knew of no specific for pneumonia. Anto-pneumococcic serum had not proved effective, and for various reasons could not influence the disease in most cases. Vaccines could scarcely do good in acute cases, especially when the system was so depressed already by the toxins that it could not react. Vaccines would only add to the toxemia. They might, however, prove of benefit in the later stages in cases showing evidences of slow resolution. The symptomatic treatment, or, rather, the treatment of the patient as indicated by his symptoms, was very simple in ordinary cases. He should rest in bed in fresh, cool air, be kept comfortably warm, be given a light diet in moderation, and receive close supervision so that prompt action might be taken in any threatening emergency. Fresh air was of the first importance, and probably better if it was cold, be-

cause it then stimulated respiration and, being more dense than warm air, supplied more oxygen in proportion to its bulk. It could do no harm so long as the patient was kept comfortably warm. If it increased cough, a mild sedative might be required. Its good effect was often shown in the improved breathing, more restful sleep, decreasing lividity, clearer mental state, and better taking of food. If such improvement occurred, the pulse became better with it, and, with the improved circulation, there would be greater excretion of toxins in the urine. The diet was not as important a question as it was in enteric fever, as the disease was of short duration. The patient should be allowed, within reasonable limits, to choose his food, care being taken that his powers should not be overtaxed for fear of abdominal distention. In the great majority of cases no further treatment was called for. The greatest danger in pneumonia was from cardiovascular and respiratory failure, due to depression of the vital nerve centers by the toxemia. The earliest signs were restlessness and insomnia, and they should be relieved as quickly as possible by stimulants, cold spongings, etc. If these means fail, opium was probably the most potent agent at our command; and no remedy was so generally useful as this in relieving cardiac failure from any cause, especially in the aged. It should be given early, preferably as morphine hypodermatically, while the bronchi are still free; since the greatest danger from its use was in permitting accumulation of bronchial secretion. If there was much dilatation of the right side of the heart, it might not be effective until the distention had been lessened. English physicians recommended for the relief of the right heart four or five leeches applied to the right of the sternum. In very threatening cases venesection was certainly more effective. If the blood were drawn in a free stream, four to ten ounces would usually give marked relief. Even in weakly, anemic patients beginning to show signs of cardiac distention much good would result from such bleeding. If thought necessary, saline solution might be given subcutaneously to replace the lost volume of blood. As to the administration of oxygen, reports of the effects were very conflicting. To be effective it should be given early, and possibly the benefit might be greatly increased by having it pass through absolute alcohol. The effect of cardiac stimulants probably depended largely on the integrity of the heart muscle. Cold applications to the chest were strongly recommended by many. Their efficacy was open to question. Not long ago it would have been considered almost criminal to omit the hot poultice. Now few regarded it with favor, and it was quite possible that before long cold applications would suffer the same loss of reputation.

Malarial Infections in the Canal Zone.—Dr. F. N. Shook, U. S. N., said that in this intensely infected focus of tropical malarial fever the most important malarial infection, from the standpoint of diagnosis and prognosis, was the estivoautumnal. Single tertian and double tertian infections were common, but quartan very rare. The principal types of estivoautumnal infections might be classified as (1) mild; (2) severe; (3) mixed; (4) pernicious, including the hyperpyretic type. Children usually stood the effects of malarial infection better than adults, but when they were attacked by a pernicious infection it often simulated cerebrospinal fever, and the autopsy showed the cerebral capillaries filled with sporulating parasites. The experience of physicians on the Isthmus emphasized the following points: (1) In tropical malaria quinine should be given either in solution or capsules, as there is danger of tablets not being absorbed. (2) If properly administered, hypodermatics of quinine rarely cause abcess. (3) Quinine will not stay the fatal termination of some types of malarial fever. (4) In cases of malarial fever in adults in the tropics which do not show pernicious symptoms the treatment with an initial dose of 20 grains of quinine, preferably in solution, followed by 10 grains three times a day, is almost uniformly successful. (5) In the treatment of malarial fever in pregnant women in the tropics the safest rule is to disregard the pregnancy and treat the malaria in the usual manner. (6) After surgical operations in malarial districts in the tropics pernicious malarial fever may develop unless a prophylactic course of quinine is first given. (7) In an examination of five fetuses from cases of pernicious malaria neither malarial parasites nor pigment were found.

Important Therapeutic Indications in the Treatment of Typhoid Fever.—Dr. J. Blake White of New York read this paper. In some preliminary remarks on diagnosis he said he would rather rely on clinical evidences, backed by his own judgment and experience, than wait for confirmation by any one or all combined of the various laboratory tests which had been proposed. While awaiting the result of such tests valuable time was often lost, and after this delay one might be led to incorrect conclusions by the return of a negative report, which was not uncommon in the earlier stages of the disease. To the extent that we succeeded in modifying the intestinal morbific process in typhoid we would not only lessen the thermic changes attending the disease, but also prevent the various complications formerly so often met with The presence of advancing and persistent intestinal lesions rendered imminent the danger of perforation, with its consequent peritonitis and death; while the blood changes, due to the absorption of the increased microtoxins, made pneumonia more probable and also added to the chances of intercurrent cerebral disease. Meningeal complication was especially apprehended in patients having the tuberculous diathesis, but with the specific antiseptic treatment which he advocated this tendency was averted when the diagnosis of typhoid was made early and the treatment promptly commenced. In the many years of his experience with the antiseptic method intestinal hemorrhage had been very rare, but when it did occur, rectified spirit of turpentine, given in five or ten minim doses in soft capsules, had never failed to control it. By judicious attention to the nutrition of the patient, to maintain the quality of the blood, thrombosis and embolism might generally be prevented. At an early stage, about the second week of the disease, when, with rare exceptions, the temperature declined under the antiseptic treatment to nearly normal, he usually gave some alcoholic stimulant, as well as strychnine, believing that, in some cases at least, convalescence was more rapid and satisfactory when alcohol was employed at this period. To await the approach of debility, especially at the decline of the fever, was not advisable; and it had seemed better to him to anticipate this with an early attention to the nutrition and a judicious stimulation. Any process of tubbing was in many instances too exhausting to be of benefit, and in some cases became a positively harmful practice, and the custom of applying chilling hydropathic treatment as a routine procedure could not, in his estimation, be too strongly denounced. His own observation of this means of reducing the temperature had convinced him that it was the most irrational method of treatment which could be devised, as it was not intended to have, and never could have, any effect upon the pathological cause of the hyperpyrexia. He was willing to admit that ablutions had some useful application in strengthening the vital powers, and therefore approved of and practised regular lavations with sterile water and alcohol, but the water must be tempered to the enduring capacity of the patient. He used lavages more as a hygienic measure than for the purpose of merely reducing the temperature, which, he believed, would yield more permanently to medication adapted to the modification of the morbific processes in the intestine which were primarily responsible for the fever. It was of vital importance that regular function of the bowels should

be maintained throughout the illness and convalescence. Under the intestinal antiseptic treatment it was not infrequently necessary to have recourse to means for exciting the bowels, but diarrhea occurring at an early stage and threatening to become an urgent symptom should be controlled.

When it became necessary to overcome intestinal apathy enemata should be given or appropriate laxatives in doses sufficient to induce only one or two movements in the twenty-four hours; or recourse might be had to irrigation of the rectum with mild warm saline solution through a Kemp tube. As to the dietary, he gave eggs, milk and light meat broths. He permitted cereals, well boiled, at any time, and the resort to solid food just as soon as the patient's condition warranted it; generally by the end of the second week, and sometimes sooner. For the causes of the fever, the toxemia from local lesions and the general blood dyscrasia, he believed no better resource was to be found than antiseptic medication. The simple temporary reduction of high temperature had little advantage unless the causes of this were removed. The fever apparently had its origin in the intestinal inflammation and the absorption of specific toxins; the first therapeutic indication, therefore, was in the direction of the use of remedies which have the essential quality of modifying and controlling this condition. No disease, in his opinion, was more manageable than typhoid fever, and he had yet to note as prompt or more constant effects from any kind of therapeutic measures in any other affection than those resulting from intestinal antiseptics in these fever cases. As soon as the diagnosis was made, or earlier if there was any doubt about the matter, the combination used by Woodbridge should be given, but in somewhat larger doses than he recommended. The best manner of administering the remedies was in tablet triturates (so friable as to be easily crushed between the fingers), which should be taken at the rate of from twenty to thirty in the twenty-four hours; each tablet to be followed by two or three swallows of some pure spring water, not aerated. After some modification of the fever had been obtained, and a general improvement observed, he gave larger doses of the antiseptic in soft capsules, one every three or four hours with larger draughts of water. Should a case not be seen until the fever had advanced so far that the patient was delirious and so unmanageable that internal medication was not possible, he gave sodium sulphoborate hypodermatically at intervals of two, three or four hours as the case might require, and subsequently began the internal antiseptic treatment as soon as the patient's condition permitted. Much depended on the nurse, who must show all kindness to her patient, be vigilant, prudent, and alert in the performance of her duty, and pay exact attention to the management of every detail. The ideal treatment of typhoid fever, then, was that which, at as little expense as possible to the patient's vitality, had for its object the reinforcement of the natural powers, thereby affording a successful barrier to the encroachment of disease; to neutralize, if not destroy, and eliminate as far as possible the causes of disease before the products of germ infection have become established in the system to such an extent as to materially impair the vital powers.

The Treatment of Leukemia by the Roentgen Ray.—Dr. Reynold Webb Wilcox of New York reported a case of this kind which he said was presented because of the difference in type based on clinical as distinguished from purely laboratory conclusions, the considerable period of observation, and the fairly constant therapeutic results which it illustrated. The patient was a medical student, Russian, and 29 years old. For ten years he had been pale, but the most noticeable symptom was shortness of breath, commencing eight years ago and lasting about two years. When he arrived in this country, in April, 1906, he considered that he was well. During the next three years he had, at times, constipation, fever (but no chills), shortness of breath, and pain below the shoulder-blade on the left side. When he came under Dr. Wilcox's observation Sept. 4, 1909, the pallor of his skin and mucous membranes was profound. The pulse was 122, compressible, regular and weak. Heart normal; Jaccoud's sign, absent; marked *bruit de diable*. The liver extended to about two fingers' breadth below the free border of the ribs. The spleen occupied the whole of the left abdominal cavity. It extended to two fingers' breadth to the right of the umbilicus; it was hard, not sensitive to pressure, and laterally slightly movable. There was no tenderness over the flat bones, and no enlarged glands were felt. Nothing of note was found in the urine. The record of blood counts, including the differential leucocyte percentage, was given; showing, for the most part, a progressively improved condition of the blood; the urine never showed the excess of uric acid usually so characteristic of the disease, nor, during the treatment by the Roentgen ray, was there observed an excess of phosphates from diminution of leucocytosis, such as had been constant in all Dr. Wilcox's other cases of leukemia.

The treatment was primarily empirical, based on the use of the Roentgen ray, and was carried out under the direction of Dr. Carl Beck. A hard tube was used, with fifteen minutes' exposure over the spleen twice or thrice weekly. On account of a slight erythema which appeared in March and lasted for ten days the exposures were omitted altogether for thirteen days and then directed upon the back for five days, after which they were continued as before. Iron was administered for three weeks in October and November. At other times arsenic, in gradually increasing doses of Fowler's solution, was given until gastric symptoms supervened; when it was omitted for a week, to be commenced in the minimal dose. In making a diagnosis between the recognized forms of leukemia—splenomedullary, lymphatic, and the mixed forms, the speaker said, there was much confusion in the literature, but, clinically, the picture was fairly clear. In this instance the massive enlargement of the spleen, taken in connection with the absence of tenderness over any of the bones, and of any enlargement of the lymphatic glands, would indicate that this particular leukemia was of the splenic type, or possibly of the spleno-medullary form, sometimes designated myelogenous. The differential leucocyte count would seem to indicate the latter. In the slowly progressive types of the affection there was more difficulty in determining where the disease originated than in the more acute forms. The more one studied the patients, the more would he be inclined to believe that the disease is seldom confined to one organ or set of organs; nor, on the other hand, was it ever as generalized as one might expect. On April 28, 1910, the lower border of the spleen was but two fingers' breadth below the free border of the ribs; its consistence was still hard, owing, doubtless, to the hypertrophy of the connective tissue during the long period of its enlargement. The pulse was 72, of good value and tension. The respiration was 22, without signs of dyspnea. The pallor had largely disappeared, and for the preceding two weeks the patient had been engaged in active employment.

What the final results of the Roentgen ray treatment of leukemia would be, no one at present could state definitely. Six years of observation had led him to believe that in this type of the disease, essentially splenic, improvement in the general health was more rapidly and surely brought about by the skilful employment of this agent than by any means which we had hitherto possessed. He also believed that both iron and arsenic still had a place in the therapy of this disease.

(*To be continued.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF GEORGIA.

May 2-7, 1910.

ANATOMY.

1. Name bones of tarsus. What bones form internal malleolus? External? What bones comprise the pelvis? Name divisions of vertebral column, and give distinguishing characteristics of cervical vertebræ.

2. What muscles aid in mastication? In deglutition? Give origin, nerve, and arterial supply of masseter muscle. What muscles compose quadriceps extensor femoris. Give origin and insertion of quadriceps extensor femoris.

3. Name divisions of alimentary canal. Name principal glands found in small intestine. What is average size of stomach? Give blood supply. Name abdominal viscera wholly covered by peritoneum. Partially covered.

4. Name and illustrate by diagram the regions of abdomen. Where in the topography of abdomen is vermiform appendix? Describe briefly Poupart's ligament.

5. Give origin of left common carotid artery. Name branches of left external carotid. Name twelve pairs nerves of special sense. Give origin and cranial exit of pneumogastric nerve. Name the three most important branches.

PHYSIOLOGY.

1. Define reflex action and give example.
2. Describe the functions of the kidneys.
3. Give the normal constituents of the urine.
4. What is meant by digestion?
5. Name the secretions of the alimentary canal, their reactions and functions.

MATERIA MEDICA AND THERAPEUTICS.

1. Ergot; its physiological action; its principal uses.
2. Cocaine hydrochloride; its physiological action; its principal uses.
3. Chloroform; define it; when is it indicated as an anesthetic?
4. Ether; define it; state the conditions that render it preferable as anesthetic.
5. Define a mydriatic, also a myotic; give examples of each, with dose for local application in each case.

CHEMISTRY.

1. Give test for albumen and sugar in urine.
2. Describe chemical test for blood.
3. Is organic material admixed to water always deleterious, and when is it?
4. Define an alkaloid, and name three principal ones used in medicine.
5. How are solutions, suspected to contain arsenic, to be tested?

PATHOLOGY.

1. Give the pathology in simple lobar pneumonia.
2. Give the pathology of pellagra, with etiology.
3. Give the pathology in hookworm disease.
4. Describe the pathological conditions in meningitis.
5. (*a*) How is fibrous tissue formed? (*b*) What tumors are composed largely of fibrous tissue, and in what part of the body do they usually occur?

PRACTICE OF MEDICINE.

1. Give symptoms and treatment of gastric ulcer, and differentiate between it and cancer of the stomach.
2. Give symptoms of appendicitis, and describe and locate the pain in (*a*) appendicitis, (*b*) renal calculus, (*c*) gallstones, (*d*) ovaritis, (*e*) cystitis.
3. Explain how to recognize in a middle-aged person, when found in a comatose state, upon what disease the condition depends.
4. Outline the area of normal liver dulness, and name the chronic diseases of the liver.
5. Scarlet fever: etiology, morbid anatomy, symptoms, incubation, invasion, eruption, complications and sequelæ, diagnosis; differentiate from acute exfoliating dermatitis, measles, rötheln, septicemia, diphtheria, drug rashes, prognosis; treatment.

OBSTETRICS.

1. Would the coincidence of diabetes with pregnancy have a harmful effect on the latter? What would you do for such patient?
2. Give treatment of a subinvoluted uterus.
3. Differentiate between putrid and true puerperal infection and give treatment of each.
4. How would you distinguish between an epileptic and an eclamptic convulsion?
5. What are the indications for the use of forceps?

GYNECOLOGY.

1. Give causes and treatment of uterine hemorrhage.
2. Under what conditions would you prefer vaginal to abdominal hysterectomy?
3. Describe technique of vaginal hysterectomy.
4. Give differential diagnosis between fluids in abdominal cavity and ovarian cysts.
5. Describe ectopic pregnancy, varieties, and operation for same.

SURGERY.

1. What conditions demand amputation of the extremities? How are amputations classified as to time of operation? What period is most favorable for amputation? Describe amputation at upper middle third of thigh, naming arteries and muscles divided.
2. What is understood by abdominal hernia? Describe an oblique inguinal hernia. Give symptoms of strangulation and method of reduction. Described an approved operation for the radical cure of oblique inguinal hernia.
3. Give differential diagnosis between traumatic coma, apoplexy, opium poisoning, and alcoholic intoxication. Describe briefly and give treatment of erysipelas. Give differential diagnosis between fracture and dislocation. Name cardinal principles in treatment of fractures.
4. Name inflammatory diseases of bone. What is understood by ankylosis? Give approved surgical procedure for establishment of joint function in ankylosis. Name and describe briefly the two most common varieties of clubfoot.
5. Differentiate between abscess and aneurysm; between hydrocele and scrotal hernia; describe approved treatment of former. What are the methods of controlling hemorhemorrhage.
Name some of the more frequent causes of secondary rhage? What is understood by secondary hemorrhage?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF GEORGIA.

May 2-7, 1910.

ANATOMY.

1. Bones of the tarsus: Os calcis, astragalus, cuboid, scaphoid, internal cuneiform, middle cuneiform, and external cuneiform. The *internal* malleolus is formed by the lower end of the tibia; the *external*, by the lower end of the fibula. The *pelvis* is made up of the ossa innominata (ilium, ischium, os pubis), sacrum, and coccyx. Divisions of vertebral column are: Cervical, dorsal, lumbar, sacral, and coccygeal. Cervical vertebræ are distinguished by a foramen in the transverse process.

2. *Muscles of mastication:* Masseter, temporal, external pterygoid, internal pterygoid, and buccinator. *Muscles of deglutition:* Buccinator, hyoglossus, styloglossus, palatoglossus, palatopharyngeus, azygos uvulæ, tensor palati, levator palati, stylopharyngeus, stylohyoid, geniohyoid, mylohyoid, thyrohyoid, digastric, constrictors of pharynx, and the intrinsic muscles of the tongue. MASSETER. *Origin:* From malar process of superior maxillary bone and zygomatic arch. *Nerve supply:* Inferior maxillary. *Arterial supply:* Internal maxillary. The *Quadriceps extensor femoris* is composed of: Vastus externus, vastus internus, rectus, and crureus. *Origin:* Anterior inferior spine of ilium, brim of acetabulum, anterior intertrochanteric line, great trochanter, linea aspera, and shaft of femur. *Insertion:* Tuberosity of tibia.

3. *Divisions of alimentary canal:* Mouth, pharynx, esophagus, stomach, small intestine (duodenum, jejunum, ileum), large intestine (cecum, colon, rectum). *Principal glands in small intestine:* Brunner's, Lieberkuhn's, Peyer's, and solitary glands. *Size of stomach* is very variable, about ten to twelve inches by four to five inches; its *blood supply* is: Gastric, pyloric, right and left gastroepiploic, and vasa brevia arteries. *Viscera wholly covered by peritoneum:* Liver, stomach, spleen, jejunum, ileum, transverse colon, sigmoid flexure. *Partially covered:* Duodenum, ascending and descending colon, rectum, bladder, and uterus.

4. See Cunningham's "Anatomy" (1909), page 1046; or Gray's "Anatomy" (1908), pages 1244 and 1246. The vermiform appendix is in the right inguinal region. For *Poupart's ligament* see Cunningham's "Anatomy" (1909), page 422; or Gray's "Anatomy" (1908), page 438.

5. The left common carotid artery arises from the arch of the aorta. *Branches of external carotid* are: Superior thyroid, lingual, facial, occipital, posterior auricular, ascending pharyngeal, superficial temporal, and internal maxillary. *Twelve pairs of cranial nerves* are: 1. Olfactory. 2. Optic. 3. Motor oculi. 4. Trochlear or pathetic. 5. Trifacial. 6. Abducens. 7. Facial. 8. Auditory. 9. Glossopharyngeal. 10. Pneumogastric or Vagus. 11. Spinal accessory. 12. Hypoglossal. The nerves of special sense are numbers 1, 2, and 8. PNEUMOGASTRIC. *Origin:* Between olivary and restiform bodies, and beneath floor of fourth ventricle. *Exit:* By jugular foramen. *Three branches:* Superior laryngeal, recurrent laryngeal, and pharyngeal.

PHYSIOLOGY.

1. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve. *Example:* The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

2. The *functions of the kidney* are: (1) To secrete (or excrete) urine; (2) the production of an internal secretion. The mechanism of the *secretion of urine by the kidneys* is twofold: (1) By filtration, most, if not all, of the fluid is eliminated, and also inorganic salts; this depends upon blood pressure, and takes place in the glomeruli. (2) By cell activity and selection, in the cells of the convoluted tubules, the urea, and principal solids are eliminated.

3. The normal constituents of the urine are: Water, urea, uric acid, urates, hippuric acid, kreatinin, xanthin, hypoxanthin; sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen, and carbon dioxide.

4. Digestion is the process by which food is converted into material suitable for absorption and assimilation.

5. The secretions of the alimentary canal are: Saliva, gastric juice, pancreatic juice, bile, and succus entericus. Of these, the gastric juice has an acid reaction; the others, alkaline.

The functions of the saliva are: (1) To moisten the mouth, (2) to assist in the solution of the soluble portions of the food, and thus (3) to administer to the sense of taste, (4) to lubricate the bolus of food, and thus (5) to facilitate the acts of mastication and deglutition, and (6) to change starches into dextrin and sugar.

The functions of the gastric juice are: (1) To change proteids into proteoses and peptones, and (2) to curdle the casein of milk.

The functions of the pancreatic juice are: (1) To change proteids into proteoses and peptones, and afterwards decompose them into leucin and tyrosin; (2) to convert starch into maltose; (3) to emulsify and saponify fats; and (4) to cause milk to curdle.

The functions of the bile are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

The functions of the succus entericus are: The secretion of enterokinase, secretin, and erepsin, which assist the pancreatic juice in digestion.

MATERIA MEDICA AND THERAPEUTICS.

1. ERGOT. *Physiological action:* Ergot stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue. *Principal uses:* To promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

2. COCAINE HYDROCHLORIDE. *Physiological action:* Local anesthetic (externally); internally it is a muscular, cerebral, circulatory, and respiratory stimulant, also a mydriatic. Its *principal uses* are: As a local anesthetic; also in paralysis agitans, chorea, and alcoholic tremors.

3 and 4. *Chloroform* is a colorless liquid, of sweetish, peculiar odor and taste, with anesthetic properties. Chemically it is trichlormethane. *Ether* is a colorless liquid, of peculiar odor and taste, with anesthetic properties. Chemically it is ethyl oxide. As a general rule, ether would be the anesthetic of choice. But chloroform may be used: (1) In hot climates; (2) when large numbers of persons have to be rapidly anesthetized; (3) in brain surgery; (4) in labor; (5) in patients who are known to take ether badly; and (6) in the conditions mentioned below, in which ether is contraindicated. The following *contraindications* for ether and chloroform are from Hare's "Practical Therapeutics": "*Ether* should not be used by inhalation in bronchitis or acute nephritis because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible. *Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

5. A *mydriatic* is an agent which causes dilatation of the pupil of the eye. A *myotic* is an agent which causes contraction of the pupil. EXAMPLES: *Mydriatics:* Atropine, homatropine, daturine, hyoscyamine, coniine, cocaine; and probably gelsemine, muscarine, hydrocyanic acid, aconite, and amyl nitrite. *Myotics:* Pilocarpine, physostigmine, and probably nicotine. Atropine sulphate, 1 per cent. solution; homatropine hydrobromide, 2 per cent. solution; cocaine hydrochloride, 4 per cent. solution; pilocarpine, 1 per cent. solution; physostigmine, ⅛ to ½ per cent. solution.

CHEMISTRY.

1. *Test for albumin in the urine:* The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture and again filtered. The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid and heated. If albumin be present a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

For sugar: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth; to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

2. *Chemical test for blood:* Boil a fragment of dried blood with a drop of glacial acetic acid on a slide; on cooling, hemin crystals separate out. If the blood stain is not recent a crystal of sodium chloride should be added with the acetic acid.

3. Organic matter in water is not necessarily deleterious; but when it is derived from sewage or other animal matter it is dangerous. The presence of nitrites is a pretty sure indication of danger.

4. An *alkaloid* is a basic, nitrogenous substance, consisting of C, H, N (and sometimes also O), capable of acting with an acid to form a salt in the same way that ammonia does. They generally have a bitter taste and an alkaline reaction. *Three examples:* Morphine, strychnine, and quinine.

5. Solutions suspected of containing *arsenic* may be examined by the *Reinsch's test*, as follows: To the suspected

fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean, dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

PATHOLOGY.

1. See French's "Practice of Medicine" (1907), page 154; or Osler's "Practice of Medicine" (1909), page 170.

2. See French's "Practice of Medicine" (1907), page 968; or Osler's "Practice of Medicine" (1909), page 384.

3. See French's "Practice of Medicine" (1907), page 497; or Osler's "Practice of Medicine" (1909), page 44.

4. See French's "Practice of Medicine" (1907), page 141; or Osler's "Practice of Medicine" (1909), page 159.

5. (*a*) "Fibrous connective tissue is developed from embryonic connective tissue cells, *i.e.* from spindle-shaped or branched nucleated protoplasmic cells of the mesoblast. The former are met with isolated or in bundles, as in the umbilical cord or embryonic tendon. The latter form a network, as in the fetal skin and mucous membrane. In both instances the protoplasm of the embryonic connective tissue cells become gradually transformed into a bundle of elementary fibrils, with a granular-looking interstitial substance. The nucleus of the original cell finally disappears."—(Klein's *Histology.*) (*b*) Fibromata or Fibroids. They *usually* occur in: Uterus, periosteum, ovary, mamma, testicle, tendons, aponeuroses.

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1907), pages 748 and 751; or Osler's "Practice of Medicine" (1909), pages 473 and 477.

Gastric ulcer is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl. *Gastric cancer* does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

2. See French's "Practice of Medicine" (1907), page 791; or Osler's "Practice of Medicine" (1909), page 514. (*a*) See French, page 792; or Osler, page 514. (*b*) See French, page 911; or Osler, page 711. (*c*) See French, page 852; or Osler, page 550. (*d*) In *ovaritis* the pain is in the ovarian region, and radiates to the back, thighs, umbilicus, and breasts; on pressure over the ovary, nausea is produced. (*e*) In *cystitis* the pain is referred to the perineum and hypogastric region, and may radiate to thighs and sacrum.

3. The following table (from Eisendrath's *Surgical Diagnosis*) gives the diagnosis:

		Middle Line	Mammary Line	Mid-axillary Line	Scapular Line
Upper limit	Deep dullness	Blend with heart dulness	4th space	7th space	9th space
	Superficial dullness		6th rib	8th rib	10th rib
Lower limit		Hand's breadth below base of xiphoid	Costal margin or some what above or below it	10th space	Blends with kidney dulness

4. The area of liver dullness is shown in the table (from Hutchison and Rainy's *Clinical Methods*):

Chronic diseases of the liver: Chronic hyperemia, chronic interstitial hepatitis (cirrhosis), echinococcus cyst, chronic perihepatitis, gallstones, amyloid liver, chronic atrophy, fatty liver, syphilis of liver.

5. See French's "Practice of Medicine" (1907), pages 315 to 325; or Osler's "Practice of Medicine" (1909), pages 130 to 140.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), pages 493 and 380.

2. See Williams' "Obstetrics" (1909), page 904; or Hirst's "Obstetrics" (1909), page 647.

3. See Hirst's "Obstetrics" (1909), pages 728 to 752, and 764 to 766.

4. For *eclamptic convulsion* see Williams' "Obstetrics" (1909), page 525; or Hirst's "Obstetrics" (1909), page 630. *Epilepsy* is not accompanied by albuminuria, has different prodromata, there is no rise of body temperature, and there is apt to be a history of previous attacks.

5. *Indications for the use of forceps* are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A. Dystocia due to (*a*) occipito-posterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. *Accidental complications:* Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both."—(From Jewett's *Practice of Obstetrics.*)

GYNECOLOGY.

1. The following (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*) is a useful classification of uterine hemorrhages, and also gives the causes of the same:

I. *Hemorrhages complicating pregnancy, labor, or the puerperium:*

A. Hemorrhages of pregnancy: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) apoplexy of the decidua or placenta.

B. Hemorrhages of labor: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of the cervix; (5) rupture or inversion of the uterus.

C. Hemorrhages of the puerperium: Caused by (1) re-

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.	DIABETIC.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.	Deep coma. Sweetish odor to breath.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.	
Pulse very slow.	Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.	
Respiration slow and stertorious.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow —may be 6 to 8 per minute.	
Temperature higher—101°	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.		
Urine normal or contians trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.	The urine contains sugar and diacetic acid.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.				

tained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

II. *Hemorrhages occurring in the non-pregnant woman:*

A. In virgins before the age of thirty: Caused by (1) uterine congestion, the result of cold or exposure; (2) endometritis; (3) polypi and fibroid tumors.

B. In married women before the age of thirty: Caused by (1) subinvolution; (2) laceration of the cervix; (3) endometritis; (4) retrodisplacements of the uterus; (5) polypi and fibroid tumors.

C. In women after the age of thirty: Caused by (1) carcinoma of the cervix; (2) carcinoma of the body of the uterus; (3) sarcoma of the uterus.

The *treatment* depends on the cause. For details see any work on obstetrics or gynecology.

2. The INDICATIONS FOR HYSTERECTOMY are given as follows: *For the abdominal operation:* All solid or cystic tumors of the uterus; cancer; uterine rupture during labor; certain conditions of puerperal sepsis; pregnancy complicated by pelvic deformity, cancer, or other serious obstacle to the passage of the child; uterine prolapse or inversion, and, incidentally, as a step in the removal of complicated suppurative conditions of the uterine appendages.

For the vaginal operation: Bilateral suppurative conditions of the appendages; prolapse, cancer, pregnancy with cancer before the sixth month; certain septic conditions of the uterus; certain rare conditions which may require the ablation of a small movable uterus.

For the combined operation: Cancer, certain complicated fibroids; failure to secure hemostasis from below.—(From *Reference Handbook of the Medical Sciences.*)

3. *Vaginal hysterectomy:* "The patient is catheterized and placed in the lithotomy position and the external genitals are thoroughly disinfected. The vagina is held open by broad retractors and the uterus is pulled down by volsella forceps grasping the cervix, while the adjoining mucous membrane is cut well clear of the disease by blunt-pointed scissors. Keeping close to the uterus, the dissection is continued on its anterior and posterior surface by the tip of the finger and short snips of the scissors, but at the sides, after division of the mucous membrane, the cellular tissue is simply pushed up as high as possible, or till the pulsations of the uterine artery are felt. The finger is finally thrust through the uterovesical fold of peritoneum, and after cleansing the vagina flat sponges are poked in around the uterus. Douglas' pouch is entered in the same manner, hemorrhage from the vaginal wound being controlled by a few catgut sutures through its cut edges, and then the finger is hooked over the fundus, pulling it down into the posterior opening and thus bringing within reach the upper border of the broad ligaments, which are seized by long-bladed clamps and divided on the uterine side. Other clamps are placed on the remaining tissues close to the uterus, which is then excised."—(Stimson's *Operative Surgery.*)

4.

ASCITES.	OVARIAN CYST.
1. Previous history of visceral disease.	1. No such history.
2. Enlargement comparatively sudden.	2. Gradual.
3. Face puffy; color waxy; early anemia.	3. Facies ovarian. Anemia absent, or later.
4. Patient on back; enlargement symmetrical; flat in front.	4. Asymmetrical until tumor is quite large; prominent in front.
5. Sitting up, abdomen bulges below.	5. No appreciable change
6. Navel prominent and thinned.	6. Navel usually unchanged.
7. Fluctuation decidedly clear, diffuse throughout abdomen, but avoids highest parts in all positions, and always has a hydrostatic level.	7. Less clear; limited to cyst; not modified by change of position. No hydrostatic level.
8. Intestines float on top of fluid; hence percussion gives clear tympanitic note over the highest parts of abdominal cavity, and dullness in lowest parts for all positions, *i.e.* areas of resonance and dullness change with position.	8. No change in areas of dullness and resonance with change of position. Dullness over cyst. Clear resonant note in all parts beyond cyst limits, *i.e.* in flanks and toward the diaphragm.
9. Vaginal touch detects fluctuation, bulging into vagina.	9. Vaginal fluctuation less clear or absent.
10. Uterus in prolapsed location, but position unchanged. Size and mobility unchanged.	10. Uterus displaced forward or backward, or laterally by pressure of cyst.
11. Hydragogues and diuretics temporarily remove the fluid.	11. Medicines have no effect.
12. Fluid light straw color and thin. Coagulates spontaneously.	12. Fluid light or dark and of varying consistency; albuminous, but does not coagulate spontaneously; may contain colloid matter.

—(From Dudley's *Gynecology.*)

5. See Williams' "Obstetrics" (1909), page 623; or Hirst's "Obstetrics" (1909), page 284.

SURGERY.

1. *Conditions which justify amputation of a limb* are: "Any injury, disease, or malformation rendering retention of the limb incompatible with life or comfort; avulsion of limb; compound fracture; compound dislocation; fracture with great comminution of bone; laceration of important vessels; extensive contusion; extensive laceration; gunshot injuries; aneurysm; effects of heat and cold; gangrene; extensive bone disease; tumors; elephantiasis; tetanus; snake bite; deformities."—(Bickham's *Operative Surgery.*)

Amputations are classified in regard to time of operating, as follows: (1) *Primary,* which is performed soon after the accident, as soon as the patient reacts from shock and before there is any fever. (2) *Secondary,* which is undertaken some time after the injury, when suppuration or bone or joint disease have supervened. (3) *Intermediate,* which is performed during the existence of the fever, but before suppuration or bone or joint disease have appeared.

The *most favorable period of amputating* is after moderate reaction has been established; in the primary period.

See Da Costa's "Surgery" (1908), page 1221. In a cross section of the thigh, at the middle third, there are severed: *Muscles,* Vastus internus, Rectus femoris, Crureus, Vastus externus, Biceps, Semitendinosus, Semimembranosus, Gracilis, Sartorius, Adductor magnus: *Arteries,* superficial femoral, anastomotic, deep femoral, perforating.

2. See Rose and Carless' "Surgery" (1908), pages 1068, 1073, 1096, 1100, 1103, and 1081; or Da Costa's "Surgery" (1908), pages 971, 999, 994, and 978.

3. See above, PRACTICE OF MEDICINE, No. 3. For *erysipelas,* see Rose and Carless' "Surgery" (1908), pages 119 and 122; or Da Costa's "Surgery" (1908), page 200.

FRACTURE.	DISLOCATION.
1. Crepitus may be present.	1. Crepitus never present.
2. Preternatural mobility.	2. Rigidity rather than mobility.
3. Easily reduced—but	3. Difficult to reduce—but
4. Deformity more liable to recur after reduction.	4. Deformity less liable to recur after reduction.
5. The head of the bone is in its proper place.	5. The head of the bone is not in its proper place.
6. The socket containing the head of the bone is not empty.	6. The socket which should contain the head of the bone is empty.
7. When rotated the bone does not move as one piece.	7. When rotated the bone moves as one piece.

The *cardinal principles in the treatment of fractures* are: Reduction, coaptation, immobilization, and suitable measures for promoting the nutrition of the part and for preventing adhesions in the neighboring joints and muscles. Compound fractures, in addition, demand: Asepsis, removal of foreign matter or damaged tissues, stopping the hemorrhage, and measures to combat shock.

4. *Inflammatory diseases of bone:* Osteitis, periostitis, osteoperiostitis, and osteomyelitis. For *ankylosis,* see Rose and Carless' "Surgery" (1908), pages 676 and 678; or Da Costa's "Surgery" (1908), pages 575 and 576. For *club-foot,* see Rose and Carless' "Surgery" (1908), page 450; or Da Costa's "Surgery" (1908), page 662.

5. For *abscess and aneurysm,* see Rose and Carless' "Surgery" (1908), page 311; or Da Costa's "Surgery" (1908), page 361. *Hydrocele:* Is pyriform in shape; the swelling is first noted at the lowest part of the scrotum; it is tense, smooth, and fluctuates; it is dull on percussion; it is *translucent;* the testicle is behind the tumor; there is no impulse on coughing. *Scrotal hernia:*

Is sausage-shaped; the swelling begins above; it is *not translucent;* the testicle is below the tumor; there is an impulse on coughing, as a rule.—(*Treatment of Hydrocele.*) See Rose and Carless' "Surgery" (1908), page 1267; or Da Costa's "Surgery" (1908), page 1201. Method of *controlling hemorrhage: Mechanical,* elevation, pressure, torsion, ligation, compression, acupressure, and forced flexion of limb. *Therapeutic,* heat, cold, styptics, and the cautery. The constitutional symptoms must also be treated: lower the head, inject normal salt solution, administer alcohol, strychnine, digitalis, morphine. For *secondary hemorrhage:* See Rose and Carless' "Surgery" (1908), page 290; or Da Costa's "Surgery" (1908), page 394.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. ..
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 3
Arkansas	F. T. Murphy, Brinkley	Little Rock	Nov. 8
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	Aug. 2
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Oct. 4
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 14
Delaware	J. H. Wilson, Dover	Dover	Dec. 13
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	Oct. 11
Florida*	I. D. Fernandez, Jacksonville	Palatka	Nov. 9
Georgia	T. H. Goss, Athens	Atlanta	Oct. 11
Idaho*	W. F. Howard, Pocatello		Oct. 4
Illinois	J. A. Egan, Springfield	Chicago	July 20
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Oct. ..
Iowa	Louis A. Thomas, Des Moines	Des Moines	
Kansas	H. A. Dykes, Lebanon	Topeka	Oct. 11
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	E. L. McGehee, New Orleans	New Orleans	Oct. 18
Maine	F. W. Swarle, Portland	Portland	July 19
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 13
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Sept. 13
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 11

Virginia	R. S. Martin, Stuart	Lynchburg	Dec. 20
Washington*	T. C. McFadden, Seattle	Spokane	Jan. 3
W. Virginia	H. A. Barbee, Point Pleasant	Charleston	
Wisconsin	J. M. Beffel, Milwaukee	Milwaukee	Jan. 10
Wyoming	S. B. Miller, Laramie	Laramie	

* No reciprocicity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State

Mississippi.—In the May examination there were 192 applicants; either the candidates were poorly prepared or the examination was very severe, for of this number only 59 were licensed.

Louisiana.—In the May examination there were 122 candidates, 29 of whom failed to pass.

State Medical Board Upheld.—The Supreme Court of Arkansas has recently issued an opinion of considerable importance to the medical profession, in which the action of the State Medical Board in revoking a license to practise medicine in the State was upheld. A lower court had enjoined the board from taking this action, but the Supreme Court reverses it and holds that the Medical Board has the right to control its membership at all times, either by granting or refusing to grant a license, or by revoking a license already granted. The license in this case was revoked because of what the board considered improper advertising on the part of the holder.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of July 9, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	452	149
Diphtheria	418	36
Measles	434	12
Scarlet Fever	177	15
Smallpox	—	—
Varicella	31	—
Typhoid Fever	51	10
Whooping Cough	48	15
Cerebrospinal Meningitis	5	5
Malarial Fever	—	—
Totals	1,616	242

Disseminated Lupus in a Child.—Little reports a girl of four and one-half years, who developed a disseminated lupus when convalescent from measles. The largest patch was on the cheek and was the size of a sixpence. There were twenty-five such lesions scattered over the back and trunk. Most of them were the size of a split pea. There was no history of tuberculosis in the family.—*Proceedings of the Royal Society of Medicine.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended July 8, 1910.

		CASES.	DEATHS
CHOLERA.			
China, Swatow	May 10–23	..	250
In vicinity from 3,000 to 4,000 deaths.			
Germany, Berlin	June 23–27	..	..
Two deaths at Ruhleben station among Russian emigrants.			
India, Calcutta	May 8–14	..	74
Madras	May 21–27	..	1
Moulmine	May 1–7	1	1
Negapatam	April 16–29	..	34
Rangoon	May 15–21	..	2
Java, Batavia	May 1–21	3	2
Samarang	May 15–21	42	32
Soerabaya	May 15–21	12	5
Russia, general		..	..
From the beginning of the epidemic in May to June 16, cases 1,491, deaths 573.			
Straits Settlements, Singapore	May 8–14	7	5
YELLOW FEVER.			
Costa Rica, San Jose	May 28–June 29	2	..
Case May 28 from Barranquilla. Case June 20 from Siguires.			
Ecuador, Guavaquil	June 1–15	9	8
Sierra Leone, Sherboro	May 20	..	Present.
PLAGUE.			
Chile, Iquique	May 22–June 4	10	3
China, Amoy	May 8–31	..	..
From 10 to 15 deaths daily.			
Chao Yang district	May 5–19	..	3,000
Mainly at Ho Peng. Present also at Chelin, Feng-chow-so, Taipushien, and Tsai-tang-shi.			
Hankow	May 15–28	2	1
India, Calcutta	May 8–14	..	87
Kurrachee	May 22–28	58	53
Rangoon	May 15–21	..	33
Japan, Formosa	May 8–28	5	4
New Zealand, Auckland	May 23	1	..
Peru, Arequipa Department—Mollendo	May 16	..	Present.
Callao Department—Callao	May 12	1	..
From *S. S. Victoria*			
Straits Settlements, Singapore	May 8–14	1	1
Turkey in Asia, Loheia	May 1–24	25	27
And vicinity.			
SMALLPOX.			
Canada, Fernie	July 15–25	3	..
Halifax	July 19–25	4	..
Pictou	July 19–25	5	..
Chile, Valparaiso	May 19	4	..
China, Shanghai	May 22–June 5	2	13

THE ETHICAL ASPECTS OF EXPERT TESTIMONY IN RELATION TO THE PLEA OF INSANITY AS A DEFENCE TO AN INDICTMENT FOR CRIME.*

By CARLOS F. MacDONALD, A.M., M.D.,

NEW YORK.

EMERITUS PROFESSOR OF MENTAL DISEASES AND MEDICAL JURISPRUDENCE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; LATE PRESIDENT NEW YORK STATE COMMISSION IN LUNACY.

THAT existing methods of presenting medical expert testimony in the trial of criminal causes is not only imperfect, but is attended with serious evils which tend to bring the medical profession into disrepute with the public, with the bar and with the courts, there can be no question. Such being the case, it logically follows that there is need of reform in this matter, and the question at once arises, How can that reform best be brought about? The method which as true physicians we would naturally adopt, in a case of this kind, would be to seek out the cause of the malady and then to endeavor to secure the removal of that cause by appropriate treatment. In looking for the causes of the evil complained of we shall not have far to seek. They will readily be found, first, in the usage of courts which permits of the selection of experts by counsel on either side without regard to their qualifications and standing, usually the only requirement being that the expert selected is willing to give an opinion in favor of that side of the case; and, second, in the absence of any standard of qualification, fixed by the medical profession, as regards special study and experience, in a given branch of medical science, which would, at least theoretically, render the would-be witness sufficiently skilled in that branch or subject to justly constitute him an expert.

The first mentioned evil could doubtless be corrected by statutory provision, not for the appointment of a "Board of Official Experts," but for the selection of experts by the Court in each case; and while it might occasionally happen that a judge in selecting an expert or experts would be influenced by other than meritorious motives, I think, as a rule, the courts could be relied upon to appreciate the responsibility attaching to their action in the matter, and to endeavor to select only men of skill and repute in that particular branch of medicine—men whose opinions would be respected by the bar, the jury and the general public as well. Indeed, the very fact that the experts had been thus selected would tend to give dignity to their position, and weight to their opinions. The experts thus selected should be permitted to have free access to all the evidence in the case, also to examine the accused, and then to state their opinion, whether orally or in writing, subject to cross-examination, the cross-examination to be limited to the matters embraced in the opinion. Their compensation also should be fixed by the court, at a rate per diem or by fee, which should be sufficient to induce qualified men to accept such service. Experts selected and paid by this method would be free from suspicion of being biased or influenced in their opinions by pecuniary considerations, while the character and the standing of those who would be likely to be selected would tend to establish confidence in the correctness of their conclusions.

In a very instructive and able paper on the subject of medical expert evidence, Honorable Willard Bartlett, Associate Justice of the New York Court of Appeals, says:

"In considering the various projects which have been put forward for improving the administration of justice, so far as expert evidence is concerned, it must be borne in mind that no matter what provision is made for the appointment of official experts, the litigants in an action at law cannot be prevented from availing themselves of the testimony of other expert witnesses. To prevent that, and restrict parties solely to the evidence of the official experts, constitutional amendments would be necessary, involving changes so sweeping as to be antagonistic to the spirit which now pervades our judicial institutions. And, if such changes in the fundamental law were possible, is it at all certain that they would be desirable? I believe that justice in the United States is generally well and honestly administered; but such a thing is conceivable as that a judge might unwittingly appoint incompetent official experts who were anything but representative of the best element in the medical profession. In what position, then, might a physician, sued for malpractice, find himself, if condemned by their opinions and unable to exonerate himself by calling as witnesses his non-official brethren whose testimony would demonstrate that the appointees of the court were wilfully wrong, or ignorantly mistaken? A man may be a good judge of law, and yet be a very poor judge of doctors. I should be sorry to have to be treated by the physicians of several able judges whom I have known in past years, and yet I am certain that in each case his physician would have been the first either of these judges would select for any official or medico-legal preferment within his power to bestow."

Respecting the second source of the evil, that is, the absence of any standard fixed by the medical profession by which the qualifications of a member to give expert testimony may be determined, the cure for that lies in the hands of the profession itself, namely, to fix a standard of qualifications based on special study and experience in a particular branch of medicine which shall entitle a member to rank as an expert in that branch, and at the same

*Read at the Annual Meeting of the American Medico-Psychological Association at Washington, D. C., May 4, 1910.

time putting its seal of disapproval and condemnation on the practice which now too frequently obtains of physicians posing as experts upon subjects respecting which they have no special knowledge or experience, relying upon their wit and the ignorance of counsel to save them from exposure.

The writer fully realizes that the present method of presenting expert testimony is by no means perfect, but he believes it is far better and more practical than any of the visionary schemes which have been brought forward from time to time by medical societies, by bar associations, and even by certain alienists. Such, for instance, as the appointment of a "Board of Official Experts" by the courts, or by medical societies, or by the Governor of the State, etc. In the writer's opinion it would be difficult, if not impossible, to devise any method that will supplant the present one short of a change in our Federal Constitution. This opinion is sustained by many if not most of the judges, who hold that a defendant on trial has a constitutional right to present any proper evidence that might aid him in his defense.

It would doubtless simplify matters, were it feasible to do so, to provide that questions of expert opinion should be passed upon by the court instead of, as is now the case, by a jury of laymen, who are not supposed to be familiar with the intricacies of psychological medicine. The spectacle of a jury of laymen being called on to decide as to which of the opinions of opposing expert witnesses respecting an obscure and difficult question of disease is correct is a *reductio ad absurdum* which has been too often pointed out to call for more than a passing mention here. This practice, unfortunately, is one that cannot be abolished for the reason that the terms of our Federal Constitution confer upon every citizen when charged with crime the sovereign right of trial by a jury of his peers.

Respecting the propositions to provide for the appointment of a Board of Official Experts, whether by the Governor of the State, by the courts, or by a State Commission in Lunacy, it is the writer's opinion that none of these methods would be desirable or acceptable, either to the medical or legal professions, or to the public, for the reason that it would savor of class legislation, which is against sound public policy. Furthermore, the prospective advantages through professional prominence and pecuniary gain, whether in fees or in salary, which such appointment would offer would lead incompetent and unworthy members of the profession to seek appointment thereon through partisan or other questionable influences. Moreover, such a board, even if fairly representative in its make-up, would be a ready target for unfriendly or hostile criticism by their less fortunate brethren in the same line of practice, who might, whether justly or unjustly, regard themselves as being discriminated against. Then, too, it would require either a very large board, or numerous boards, to provide a sufficient number of experts in the various branches of medicine, surgery, and chemistry, in which medico-legal questions arise. Says Mr. Justice Bartlett, in the paper referred to: "There is not likely to be any radical change in a matter of legal procedure like this, without the approval of the bar, and I doubt very much whether the bar would approve any legislation which would enable the courts or any other appointing power to create a privileged class of expert witnesses."

For the reasons herein set forth, it would seem to the writer that the most practical solution of the difficulty would be to make statutory provision for the appointment by the court of from one to three experts whenever occasion arises, the law to provide that only physicians of repute in the particular branch of medical science to which the question for expert opinion relates shall be appointed, these experts to have full and free access to all the evidence in the case as well as to the defendant, for the purpose of examination, and then to submit to the court for transmission to the jury a written report, setting forth their conclusion and the facts in evidence on which such conclusion is based, the cross-examination of the experts to be restricted to matters embraced within their direct statement of facts and opinion, and the compensation of the experts to be fixed by the court. The writer is well aware that lawyers would raise objection to this manner of selecting experts, on the ground that a defendant is constitutionally entitled to the selection of his own witnesses and to call any witnesses whose testimony would tend to sustain his case—a right which can neither be taken from him nor abridged. This objection, however, would be met by the fact that counsel would still be permitted to call experts in addition to those selected by the court; though it is safe to say the opinion of the official or court experts would far outweigh any differing opinion that might be offered by experts selected by counsel. It goes almost without saying, too, that this method of selecting experts would always be satisfactory to prosecuting attorneys.

There is another point in connection with this subject, which in the writer's opinion should receive not only the attention of this association, but of the general medical profession as well, for the reason that it is frequently a source of discredit to our profession. This refers to the unprofessional practice of certain medical men—mostly pseudo-experts—acting as medical advisor to counsel and expert witness in the same case. To observe, as the writer has often done, medical men sitting in court at the elbow of counsel, actively engaged in taking notes and preparing or suggesting questions for the latter to put to the witness; also framing questions for the cross-examination of a fellow practitioner and otherwise openly assisting counsel in his efforts to break down the opposing side, and subsequently taking the witness stand for that purpose, is, to say the least, deplorable. If a physician is to appear as an expert witness, he should keep away from counsel while in court and take no part in the conduct of the case which would put him in the attitude of assistant counsel or of a biased or interested party. In the first trial of Thaw the writer was selected by District Attorney Jerome to assist him in the preparation of the medical branch of the trial, a service which he accepted with the distinct understanding that he would not appear as a witness in the case.

Anent this subject Mr. Justice Bartlett in the paper referred to says: "In my opinion the law can do very little toward making experts or anybody else honest or upright or capable in their particular pursuits. I look for reform rather in the direction of the development of a higher sensibility on the subject in the medical profession itself. It is entirely possible for the doctors of this state or country to so frown upon the practice of acting as medical counsel and medical witness in the same case as to stamp it out completely. There is nothing to prevent a physician who is asked to see a case with reference to giving testimony as an expert from exact-

ing an agreement that his remuneration shall in no wise depend upon the opinion which he may form upon making the desired examination; or in other words, that he shall be paid just the same and just as much whether his conclusion is agreeable or disagreeable to the attorney who seeks his services. No attorney will refuse to consent to this course unless he is desirous of influencing the doctor to take one view of the case rather than another, because in that event he will get paid while otherwise he may get nothing. A tempter of this sort should be shut out of the doctor's office with no gentle slam of the door. And so in many other ways which might be suggested some of the most serious evils of medical expert evidence may be effectively dealt with by 'reform within the party.'"

Respecting the sweeping condemnation of medical expert testimony in which the courts, the public press, and to some extent the medical press are wont to indulge Mr. Justice Bartlett, referring to the common assumption by lawyers and doctors that courts and juries would be sure to get at the truth if the expert witnesses on one side could only be induced to agree with the expert witnesses on the other, cites a case in point which occurred in California, in which the plaintiff, a married woman, was injured in an accident upon the defendant's railroad. In the suit which she brought against the railroad company to recover damages, one of the principal questions was the extent of the injuries which she had sustained. She had been examined by three or four medical men in her own behalf and by three or four other medical men in behalf of the defendant. Both those who testified for the plaintiff and those who testified for the defendant agreed that the plaintiff was suffering from a uterine or ovarian tumor, but there was a difference of opinion as to whether the tumor could have been produced by the plaintiff's fall. A verdict of $20,000.00 was rendered against the railroad company. Ten days after the trial the plaintiff gave birth to a child at full term, although still-born, and it was admitted that there had been no tumor whatever! 'Since the time of Mr. Pope,' says the Supreme Court of California, "it has often been inquired "Who shall decide when doctors disagree?" This case shows that serious error may lurk in their conclusions even when they have agreed. Such an occurrence, if narrated in a work of fiction, would be criticized as so improbable as to be ridiculous; but there is no romancing in the cold type of a volume of modern law reports. The possibility of so serious an error being committed by so many respectable members of the medical profession—for the court speaks favorably of their standing—tends to afford some justification for the popular distrust with which medical expert evidence is often regarded." Continuing, the learned justice says: 'In reference to this matter, however, I desire to express my dissent from the sweeping condemnation of medical experts in which the courts so often indulge. There is scarcely a case where expert evidence is taken in which some of the experts are not perfectly honest. They do not deserve denunciation merely because other experts are dishonest, or because it is often difficult to tell the false from the true. The medical profession itself must help us to make the distinction between the two classes easier. However objectionable are some of the aspects of medical expert evidence, it cannot be dispensed with in the administration of justice. Let us remedy the evils, but, while we are endeavoring to do so, let us avoid that exaggerated denunciation which is calculated to convince the community that no surgeon or physician who takes the witness stand as an expert is worthy of belief. Such teaching is a libel on the most unselfish profession in the world.

"What I have said thus far has been so largely in the nature of destructive criticism that I may naturally be asked whether I have no remedy to suggest for the manifold evils in regard to medical expert evidence which are generally recognized in both professions. In concluding this paper, let me add a few observations in answer to this question. I should be sorry to feel that the prospect of reform was hopeless. There is one direction in which it seems to me brighter than any other. You have a code of medical ethics which every physician and surgeon is bound in all professional honor to observe. By that code you regulate your own conduct in the practice of medicine, and insist that those who join the ranks of your profession from year to year shall agree to regulate theirs. No statute could practically be more binding. Why may you not extend its provisions so as to embrace the conduct of the medical man when he assumes the rôle of the expert witness? The matter is absolutely within your own control. You can declare in your code that a certain course of action on the part of a medical expert shall be deemed honorable and professional, and that a certain other course of action shall be dishonorable and unprofessional. The first steps in enacting such amendments in your professional law would necessarily be tentative. Mistakes would be made which you would have to correct. Rules from which the most good was expected might prove useless, and others which promised much less might prove to be the most effective of all. But in making them and changing them you would be independent of the Legislature; you could act solely for the good of your profession, untrammeled by official influence or power; and so far as you desire advice from the bench or bar I am sure it would be gladly afforded. A signal advantage of dealing with the subject in this way is that it would involve no interference with existing rules of judicial procedure. The rights of litigants or the manner of trying lawsuits would in no wise be affected. The needed reforms would be brought about by the compulsory operation of your own code of ethics acting personally upon each member of your profession. That code, amended as I am sure it might be if the physicians and surgeons of this country took the matter seriously in hand, by commanding medical experts to do what is right and subjecting them to professional censure and obliquy if they did what was wrong, would be more efficacious than any law on the subject which any legislature could enact. It would be your own law, adopted by yourselves for yourselves, and it would have that powerful sanction which belongs alone to laws which are a natural growth out of the conditions which lead to their adoption. To the action of your profession in some such way as this I look with more confidence than anywhere else for the ultimate accomplishment of all that is desirable in the improvement of medical expert evidence."

In connection with this branch of the subject the writer would take occasion to suggest that it is the duty of the medical profession to raise its voice in solemn protest against the tendency which has lately grown up to heap upon it ridicule and abuse because "doctors disagree," and that consequently all, or substantially all, doctors are dishonest. As a matter of fact, doctors are no more prone to disagree than

any other class of individuals where matters of opinion are involved. On the other hand, lawyers are notorious for their disagreements. In fact, in every case that is tried in court we find the contention of counsel on one side is diametrically opposed to that of the other side; and this, too, on substantially the same state of facts. Then, too, judges are also notorious for their disagreements, the higher courts frequently reversing the court below, clear up to the court of last resort; and it is safe to say if there were still a higher court it would be found overruling the Court of Appeals. How frequently, too, we find the body of judges constituting the appellate courts divided in the decisions they render, the issue being decided oftentimes by a bare majority of one. And yet nobody would think of suggesting that these judges are dishonest simply because they happen to disagree.

Mr. William A. Purrington, an eminent member of the New York bar, and one of large experience in medico-legal matters, in a recent paper referring to the disagreements of judges whom he characterizes as "that great body of experts who rarely if ever go upon the witness stand, yet are always under a continuing oath, and in every case from the facts before them render their opinions as to the law. When they give an opinion, whether it be right or wrong in our opinion, it is of binding force until set aside; and that is more than can be said of yours of the faculty, or ours of the bar. I have sometimes wondered whether those judges who have been most denunciatory of the differing conclusions at which reputable medical experts have arrived upon the facts in evidence have reflected that they, too, belong to a body of experts in the law, whose members often differ, very honestly and ably, in drawing conclusions, even from agreed facts." Mr. Purrington then goes on to cite, in illustration of his point, "The recent medical case of the People vs. Hawker (14 App. Div., 188; 152 N. Y., 234; 170 U. S., 189) wherein the facts were agreed upon, and the only question involved was one of law, whether a statute forbidding one convicted of felony to practise medicine could apply to a licensed physician so convicted prior to its enactment; in other words, whether the statute was *ex post facto*. The trial judge decided negatively. The Appellate Division of this department, by a vote of three to two, reversed him; the Court of Appeals in turn reversed the Appellate Division, two of its judges dissenting; and finally, the Supreme Court of the United States, after two arguments, affirmed the Court of Appeals, three of its members dissenting. Surely no one would presume, because of these differences of opinion, to doubt for a moment the ability, the learning, the absolute honesty of these various experts of the law; and it is equally manifest that the frequent differences of opinion among medical experts—the only class we are now considering—should not of themselves alone justify the criticism so freely made."

District Attorney Jerome, in a recent public utterance, declared "No man has had more experience with experts than myself during the eight years I was district attorney, and during that time I recall only one man whose testimony was radically dishonest. Only one of these cases received great public attention, and that was on account of the scandals connected therewith. These scandals were not, however, save with one exception, due to dishonest expert evidence, but to judicial incompetency. It does not follow because there are alienists who lie on the witness stand that all medical expert evidence should be abolished, any more than that because some lawyers coach witnesses to a point that amounts to subornation or perjury, the conduct of criminal cases should be left entirely to the judge. I have referred to the Thaw case and you all know whom I mean when I say that there was one man who testified on that occasion, who, in view of his testimony in that case, and in view of his evidence since and his own written report, would be expelled from the profession, if you gentlemen had the power to disbar him. I may say that in every case during my term of office the opinion of the experts retained by the State was justified by the subsequent clinical history."

The Hypothetical Question.—Respecting the hypothetical question it must be conceded that it is a very difficult proposition with which to deal, especially so far as relates to any improvement or proposed modification of existing rules of practice relative thereto. The rules of evidence provide for the hypothetical question and the courts have held that while such questions must contain nothing that is not contained in the evidence they do not prohibit the omission of any facts in evidence which counsel may in their discretion see fit to omit. Hence it frequently occurs that counsel sifts and omits from his hypothetical question certain important facts in evidence which if incorporated therein would tend to weaken or discredit his contention, and he is prone to include in his question only such facts in evidence as he thinks will tend to prove his case. Consequently, the hypothetical question usually is a one-sided affair. The writer has frequently suggested, and sometimes insisted, that the question to be submitted to him should embrace a fair résumé of the whole evidence, and when this plan has been followed he has usually found that he could answer the question thus constituted as consistently and to the same effect as he could have answered what might be termed an *ex parte* question. This, it seemed to the writer, has tended to strengthen his testimony in the estimation of the court and of the jury, and at the same time to relieve him from appearing to be an unfair, one-sided and partial witness.

The Legal vs. the Scientific Definition of Insanity.—The legal definition of insanity as a test of responsibility for criminal acts, that is, the so-called "knowledge of right and wrong" test, presents a feature of the administration of the criminal law in which the legal profession has made little or no progress for more than half a century, or since the legal definition of insanity was formulated by the English judges in their decision in the celebrated McNaughten case, in 1843. In fact, the Criminal Code of the State of New York to-day defines insanity in substantially the same language as that used by the judges in the McNaughten case, namely: "A person is not excused from criminal liability as an idiot, imbecile, lunatic, or insane person, except upon the proof that, at the time of committing the alleged criminal act, he was laboring under such a defect of reason, as either (1) not to know the nature and quality of the act he was doing; or (2) not to know that the act was wrong."

As alienists we can hardly accept this "right and wrong" test as regards responsibility for crime. But as this is the law of the State of New York, and in many other states of the Union, we are obliged to abide by it. In fact, as experts, we have nothing to do with the law. Our function is simply to de-

termine, if possible, the mental condition of the accused at the time the act was committed—a purely scientific question. Now every alienist knows perfectly well that this so-called legal definition is unscientific and way behind the age, and that, in this matter, the law has not kept pace with the progress of medical science. Those who are familiar with the phenomena of mental disease know perfectly well that in a large majority of cases in which the plea of insanity is offered as a defense to an indictment for crime the accused knows the difference between right and wrong in the abstract—a large majority of the so-called "dangerous" or "criminal insane" being paranoiacs. We know that paranoiacs as a rule converse coherently and plausibly and that they reason logically respecting their delusional ideas, but that they always reason from wrong premises, the mental condition being one of gradually developed delusional ideas of the systematized variety, without marked mental deterioration or clouding of consciousness. So that, in most cases, with us the question is, not whether the individual knew the nature and quality of the act he was doing and knew that it was wrong, but whether he had the power to control his act and to resist the impulse to do the wrong, or whether he was actuated by delusion which supplied the motive, impelling him to do the act.

Now, if every form and stage of mental disease were invariably attended by a loss or suspension of the knowledge of right and wrong, such as usually occurs in extreme types of mania, melancholia, paretic-dementia, etc.—forms or stages of the disease which are usually characterized by mental aberration so marked as to bring them easily within the ken of unskilled observers who would readily recognize the symptoms which in themselves furnish presumptive evidence of a lack of power to distinguish rationally between right and wrong, no valid objection could be raised to the present legal test of insanity, wrong in principle though it be, for the reason that its practical effect, as applied to the class of cases referred to, would be to establish irresponsibility, in substantially every case, regardless of the nature of the act committed. Unfortunately, however, but a small percentage of the insane who come within the jurisdiction of our criminal courts belong to the types of insanity referred to; this class of persons, being, usually, not homicidal, seldom commit, or attempt to commit, homicide, or what is technically known as crime against the person. In other words, such persons do not belong to the "dangerous insane," consequently there is little or no difficulty in such cases in determining the question of responsibility, for the reason that they readily fall within the legal conception and definition of mental disease. It is the obscure and doubtful cases that so frequently puzzle our courts of criminal jurisdiction, and these are drawn almost wholly from the ranks of the paranoiacs; and this class, as we all know, frequently commit crime from motives similar in character to those which actuate sane persons, namely, revenge, vindication of personal honor, defense of life or property, etc. But if we seek the bases of these motives we shall find that, unlike the motives of the sane, they are not founded on reality, but are the offspring of a diseased or disordered intellect, a psychopathic state which has deranged the psychical apparatus, so to speak, and left it awry, even though the logical apparatus remains intact. The paranoiac is prone to premise falsely and to morbidly misinterpret the conduct and motives of those about him. And while he may reason logically, he reasons from wrong premises and in a way that a sane man would not do. Such being the case, it frequently happens that, under the requirements of our criminal code, we are put in the false position of testifying in effect that a defendant was sane legally, that is, that he knew the nature and quality of the act he did, and knew that it was wrong, when, as a matter of fact, we know that he is insane and irresponsible, according to the teachings of medical science.

It has been suggested that the most satisfactory way to deal with criminal cases, especially capital cases, in which insanity is pleaded as a defense, would be to keep the question of insanity out of the case entirely during the trial, and to allow the jury to pass only on the question of the guilt or innocence of the accused, irrespective of his mental condition; then, if the defendant be convicted, let the court appoint a commission of competent alienists to determine his mental condition, and whether he is punishable by reason of mental disease or not. Such a commission could be relied upon to reach a sound and harmonious conclusion. The writer does not pretend to say that this method would be feasible, but it would at least seem to offer an improvement on the present method of determining the mental condition of a defendant which puts upon a jury of laymen, who, presumably, are not familiar with the phenomena of mental disease, a responsibility which they should not be called upon to assume. If the function of the jury were restricted to a finding on the facts, that is, if the defendant committed the act as charged, and, subsequently the question of his mental condition were determined by competent alienists appointed by the court, it is believed that the finding of such a commission would be accepted by the public, both lay and medical, and that there would be no danger of a miscarriage of justice. If this method were feasible under the constitution it would seem to furnish the best solution of expert testimony in criminal cases in which the mental condition of the accused is in issue.

"So long as mind and intention shall be held to constitute the foundation of legal responsibility," says Ordronaux,* "so long will their absence be likewise held to exonerate from all imputability of crime." In other words, before there can be guilt, there must be mental competency to concoct it. And yet despite this truism, there still exists in both lay and medical circles a wide diversity of opinion as to how far insanity should be held to absolve from criminal responsibility. These diverse and even opposite views have existed from the time that Lord Hale undertook to define the exact extent to which the mental movements were influenced by insanity and its consequent effect in impairing the responsibility of its victims down to the present time. As a result of his investigations, Lord Hale concluded that, while the milder forms of insanity might not be sufficient to excuse one from responsibility for criminal acts, a sufferer from the severer types of the disease would be excusable for any crime he might commit under its influence. Subsequently, in 1843, the English judges, in response to questions put to them by the House of Lords, in connection with the celebrated McNaughton case, formulated a definition or test of insanity which

*Judicial Problems Relating to the Disposal of Insane Criminals, by John Ordronaux, M.D., 1881.

was substantially the same as the one put forth by Lord Hale. In the language of the learned English judges: "To establish a defense on the ground of insanity, it must be clearly proved that at the time of committing the act the accused was laboring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing, or, if he did know it, that he did not know he was doing what was wrong." From the time this judge-made law was promulgated down to the present day our criminal courts, with their traditional regard for precedent, have generally accepted it blindly and propounded it to juries in almost identical language, notwithstanding the emphatic protest of medical men that such test is in direct conflict with the teachings of medical science and false in its application to the mentally unsound. As before stated, the Revised Code of Criminal Procedure of the State of New York, Section 21, defines insanity in precisely the same terms as those used by the English judges in the McNaughton case. Thus it appears that our lawmakers, blindly following the dictum of Lord Hale and his successors on the English Bench, and ignoring the teachings of medical science, have undertaken to determine by statutory enactment what insanity is and to define the conditions of responsibility in mental disease by declaring in law what shall be rather than what is, and have thus given us a test which is based on a misconception of the true nature of insanity, and so narrow in spirit and so untenable in reason that every experienced alienist must regard it as artificial, arbitrary, and fraught with danger to humanity and to the ends of justice. "The true test of irresponsibility," says Forbes Winslow, "should be, not whether the party accused is aware of the criminality of his actions, but whether he has lost all power or control over his actions." "Make the man's power of controlling his actions the test," says Clouston. "With that view every medical man will agree."

Hence it would appear, if medical science is correct, that the real question of fact for the jury to determine in criminal trials where insanity is alleged is: Did the accused at the time he committed the act of which he is charged have sufficient mental capacity to appreciate rationally the nature and consequences of the act he was committing, and, if so, had he sufficient power of will to enable him to choose between doing it and not doing it? It must be admitted that a correct solution of this question, involving as it does human life and liberty, is of vital importance; and, inasmuch as it relates directly to disease, the facts upon which its solution depends can properly be interpreted for the jury only by competent medical testimony. If this were done it is believed that much of the conflict of opinion in our law courts respecting the question of responsibility in criminal cases where insanity is offered as a defense would disappear.

Thyroid Enlargement in Rheumatism.—Clemens calls attention to the frequency of enlargement of the thyroid gland in rheumatism in childhood, and suggests that this is a diagnosis sign of value. The time of appearance of the thyroid enlargement varies. In some cases it precedes all other manifest signs of rheumatism. Again it appears as the fourth or fifth link in the rheumatic chain, and at other times it persists in association with established chronic endocarditis after all other rheumatic manifestations have disappeared. The degree of enlargement while not great, is sufficiently pronounced to give an unnatural fullness to the neck, which is unmistakable when viewed laterally.—*Archives of Pediatrics.*

THE ANOMALIES OF OCULAR DOMINANCE.

AND

A. C. DURAND, M.D.,

ITHACA, N. Y.

If one alternately closes or covers the eyes while looking at an object in the room he will notice it "jump," or change position. It is easy to demonstrate the fact that the eyes, being two or more inches apart, must form two images of one object, differing topographically in certain ways and relations. The fact has many startling, practical significances, as was long ago pointed out.

One constantly observes that many people, especially presbyopes, or those over 40, habitually close one eye, usually the left, when looking definitely at some object or when observing something with care. When the hunter sights his gun, when the boy uses his spyglass, when the carpenter sees if his board is level or straight, when the young microscopist or ophthalmoscopist uses his instrument, the disused eye is closed. And it is "the dominant eye," usually, that is put to single use, the poor image of the nondominant one being wholly excluded by closure. There are more blind or half-blind, more injured, left eyes than right eyes, and the vast majority of righthanded people have, of the two eyes, poorer-seeing left ones. These facts should have led oculists to the truth, and to its significance, the law of righteyedness and lefteyedness, or of what we have called the "dominance" of one eye.* In athletic and sporting circles the crude recognition of the truth has resulted in the term "the master eye," the single eye which governs and rightly estimates acts, and the exact localization of objects, and which coordinates all bodily actions with accuracy and speed. One may even catch glimpses of the unconscious knowledge or experiences which have brought into use such colloquial or proverbial expressions as "Keep your eye on him," "Keep your eye peeled," "A beautiful eye," "Mind your eye," "All in your eye," "Run your eye along the line," "An eagle eye," "The eye of faith," "A spiritual eye," "The eye of the law," "Your weather eye," "An eye to the blind," "At first eye (or sight)," "God's eye," "The common eye" (of the people), "He has him in eye," "A friendly eye," and a thousand such expressions of poets and writers in all time. The great superstition of "the evil eye" will be found to have arisen from a similar source.

From the prior and subsequent histories of perhaps a hundred such patients as will be described in later pages we conclude that:

1. Perhaps 3 per cent. of eyestrain sufferers are troubled with the disorders consequent upon the anomalies of ocular dominance. Possibly 8 per cent. of little children are at first lefthanded. Of these, in about 75 per cent., there has been a mistaken and harmful attempt on the part of parents, teachers and school-fellows, to make the child write, sew, or hold the knife, with the dextral hand. In the larger portion of this class the attempt has been harmfully, partially, and awkwardly successful. In a smaller number of cases this, despite all punishment and suffering, has been unsuccessful, and the child has luckily remained normally lefthanded.

*See "Righthandedness," etc., J. B. Lippincott Company, 1908.

2. Except in so far as it has influenced the primary shapes and sizes of the eyeballs, heredity has no influence in the production of righthandedness and lefthandedness. Left-handed parents will have right-handed children and grandchildren in about the same proportion as righthanded parents—*i. e.*, approximately 92 per cent.

3. Righthandedness and lefthandedness arise in the first year or two of life, and are caused by the dominance respectively of the right or of the left eye.

4. Dominance is dictated and established by the better vision of the right or of the left eye, in the great majority of cases, by the less incapacitating ametropia existing at the time of the beginning of the habits of willed arm-and-hand actions. In relatively 92 per cent. of infants the right eye is the better or easier seeing eye, and in 8 per cent. it is the left.

5. The attempt to change the establishing or established habit of lefthandedness in a child inevitably produces disease of many kinds, awkwardness, liability to accidents, incapacities, and it handicaps in all the subsequent life. It decidedly lessens the validity of the person in the civilized "struggle for existence." The difficulty and partial or complete unsuccess of the attempt shows that something far more than mere "handedness," or handiness, is at work to prevent it. This something is the preceding and causal dominance of a single eye. It would be a crippling disadvantage to be "ambidextral," and fortunately there is no person in the world who is really so. All that is usually attempted—and at what a reckless cost—is to make a left-handed child write with the right hand. There might possibly be a somewhat less hurtful success if the training of righthandedness were begun at the age of six months or a year. But even then no attempt would be entirely sucessful except it were begun by the attempt to make the naturally better left eye into one seeing less correctly and easily than the right eye. This would be a pretty hard job! More fundamental, also, is the necessity of governing dextral and sinistral actions of one side of the body by motor and sensory centers in diverse cerebral hemispheres. Since evolution of the bodily organism began vertebrate action has depended upon the government, innervation, and coordination of dextral bodily organs by centers located in the sinistral side of the brain, and of sinistral bodily organs by brain-centers gathered in the dextral hemisphere. The ambidextralists and other trainers of the poor lefthanded should start by rearranging and fusing into unity the dual brain. Their present aim is in fact an attempt to make two speech-centers instead of a single one. But the writing center is, and must be, in close contiguity to the speech-center, so that also must be doubled. One fancies that God is wiser, and that their interference is quite futile. The public-school laws (of New York City, for instance) should be repealed which forbid a lefthanded child to write with the left hand.

6. Reversals of dominance in a relatively small number of individuals, as life goes on, are inevitable. Plainly, if the hitherto dominant eye is lost or blinded by disease or by injury, the remaining eye must take up dominancy as best it may. And there follows the certain revolution in brain-function, the awkwardness, the dangers, slowness of mental and physical action, the inadaptabilities, which must then be slowly and imperfectly overcome as the patient best may effect. There is necessarily a greater or less incompatibility in all expert tasks, in fact, a halting and difficult readaptation to the old duties and necessities—old habits must be undone, and new habits slowly established.

The effective life-problem at once becomes a very different one. But the decided lessening, from any cause, of the greater ease and acuteness of vision of the hitherto dominant eye, to a great extent brings about exactly the same results as the absolute loss of the eye. Dominance is then transferred to the previously second best eye, especially if this occurs early in life, when less fixity of habits and of cerebral mechanisms make the transfer more easy. A hundred practical problems and considerations arise at this point. Organisms, of course, differ, even at the same relative age of the life, in plasticity and possibility of changing habits. Occupations also make myriads of grades and kinds of exactions upon workers.

A frequent cause of reversals of dominance is the changing of the errors of refraction during youth, so that the visual acuteness of the hitherto dominant eye becomes relatively so poor and unreliable that dominancy must be transferred to the other. The tragical results will then depend upon the time of life at which this occurs, the plasticity of the neurological and the habit-mechanisms, the occupation, etc. These refractional changes account for most of the anomalies of dominance. We have had about a dozen patients who are right-handed but left eyed, because of much higher and incapacitating refraction error in the right eye; two or three others were lefteyed with the higher defect in the left eye; while there have been about a dozen with righthandedness and lefteyedness, but with the errors about the same in each eye. Careful refraction under mydriasis is of course necessary to ascertain the facts with accuracy.

In general, one may say that the established dominance will persist even though the visual handicap of the dominant eye is one-quarter or one-third less than that of the nondominant one. In the beginning of the growing handicap of ametropia in the dominant eye, scientific spectacles, which restore or retain its former ease and certainty of visual sharpness, will, of course, keep it in dominance, and avoid the otherwise certain ensuing troubles. If only 1 per cent. of those wearing or needing correct spectacles have not exactly the kind that will preserve the habitual dominance, there must be hundreds of thousands of American, and more of foreign, patients who are needlessly suffering reversed dominance.

Other agencies which may affect the vision of the dominant eye and transfer its dominance to the other eye are: Keratitis, or leucoma; iritis, cataract, retinitis of any kind; ophthalmovascular choke with fading image worse in the dominant eye; heterophoria, surgical operation, etc., etc. Sometimes, indeed, the surgeon may be able to preserve the old dominance of an eye by excessive attention, by choice of an operative procedure, etc.

Lastly, to be remembered are the cases of injury, disease, etc., of the hand, arm, etc., habitually coordinated under the direction of the dominant eye, whereby the writing, sighting, localization, etc., have been compulsorily transferred to the reverse hand or side of the body, leaving the established ocular dominance unchanged. In such cases the patient must play billiards and other games, sight a gun, write, etc., with the hand hitherto unused for

such expert tasks, and under the greatest difficulties. So great are such handicaps that a number of patients, although lefthanded or lefteyed, still shoot from the right shoulder, but sight with the left eye, the right being awkwardly depressed below the level of the gun.

The symptoms of anomalous dominance are peculiarly subtle and hidden and hard to elicit, because difficult for the patient to remember or even to bring to consciousness. And they are rendered more difficult of discrimination because they are almost always interwoven with and concealed by the thousand peculiar and ever-variant symptoms of ordinary eyestrain. In children, especially, there is likely to be such an inability to see objects in their proper relations and placings that there is much tearing of clothes, stumblings, hurtings, and accidents of many kinds. As caution is learned there ensue a halting and slowness of action, a seemingly unnatural and even stupid lack of decision or action, especially of speech. This may develop into stammering or stuttering, due to the necessity of correlating the centers of articulate speech, sight, etc., located in opposite cerebral hemispheres. There may be an astonishing fatigue in reading or even positive inability to read. All sorts of awkwardness and impossibilities of doing certain things may become manifest. We could list a hundred odd symptoms—inability to think and write at the same time; becoming "dazed" or blank-minded when trying to write, or to do certain things; absurd hesitation and long calculating in sewing, or playing games, in waltzing, etc.; confusion of mind, inversion of words or letters; willing one thing and doing another; mirror-writing; lapses of memory and attention; inexplainable awkwardness and absent-mindedness; sulkiness; explosions of temper, "nervousness," morbid aloofness, even "hysteria," etc., etc. For instance:

Y. J., a girl of 12, had two years ago a moderate compound hyperopic astigmatism, alike in the two eyes, with fair acuteness of vision. She was lefthanded, but was compelled to write with the right hand. She had a good mind, but was one or two years behind other girls of her class and age in all school studies except arithmetic. She reversed words having similar letters or sounds, saying *was* for *saw*, *on* for *no*, *of* instead of *for*, etc. For four years she had stuttered or stammered badly, or had a most noteworthy slowness of speech, a preceding period of provoking silence, preparation, and difficulty in bringing thought to speech. We asked her to try to write with her left hand, and in two weeks she could write as well with this hand as with the right after the years of conscious effort. She sewed with the right hand, brushed her hair with the left, threw ball equally badly or well with either hand, etc. The most noteworthy and illuminative symptom was this: When asked, or trying to read, the first two or three lines are got through with at a good rate of speed; then the reading becomes slower and more difficult, and before the bottom of the page is reached she has to spell each letter of every word before she is able to understand or speak it. She has 1.50 D. subnormal accommodation and moderate compound hyperopic astigmatism alike in the two eyes. With the bifocal spectacles ordered most of her symptoms have disappeared, and others lessened. Some "confusion" persists, however, and mixing of words. Where before there was morbid sobriety and joylessness, there is now normal gaiety and laughter. This girl is still a righthanded writer, by preference, but is now right-eyed for writing; she does not stutter, has "caught up" in school, etc.

M. P. J., aged 37, was a left handed child, but by a vast deal of trouble her mother compelled her to write and sew righthandedly, and to hold the knife in the right hand, in eating. When grown up she began sewing with the left hand, and now "hates sewing." Her husband is lefthanded, but their three children are righthanded. In speaking there is always noticeable a hesitancy and halting, especially when giving orders or directions. As a child she had many accidents owing to awkwardness, and faulty localization of objects, and was always tearing her clothes. She has exceptionally great fatigue in going to picture galleries, stores, etc. Her error of refraction is at present:

R. + s. 1.25 + c. 0.25 ax. 50° = 20/20
L. + s. 1.25 + c. 0.25 ax. 130° = 20/20 +

K. K., aged 32, has had a life of strange and great suffering—migraine, vomiting, insomnia, swooning, "swelling of eyes," and of flesh about eyes, suicidal attempts, "nervous prostration," trial at convent life, at insane asylum, etc., etc. She has always had great confusion of mind, of speech, and of action, for instance, "putting flowers into the ice-box instead of the butter." She has been drinking excessive amounts of coffee. She was lefthanded as a child, but was forced into righthanded acts and habits, especially as regards writing. By our advice she undertook lefthanded writing again, after we had given her correct spectacles, which brought the left eye into possible function. Formerly she wrote a very large or coarse hand, but now writes very fine or small letters. The style of the writing or shapes of the letters also differ markedly. She is now using the left hand more unconsciously. She does not get confused or "mix up her acts," as formerly, and there are less mistakes in the choice and use of words. Her memory is greatly improved. Her error of refraction at present is:

R. + c. 1.50 ax. 105° = 20/20 +
L. + s. 0.12 + c. 1.87 ax. 90° = 20/20 +

She had been wearing lower power cylinders at axes 140°—lenses that increased instead of diminishing eyestrain, and which threw the left eye out of function.

Two patients are righthanded but lefteyed. They shoot from the right shoulder but sight with the left eye, the right being depressed below the level of the gun and out of use. Two other patients thoroughly lefthanded and lefteyed also shoot from the right shoulder with the left eye, the right depressed in the same way.

R. W. has a very high degree of compound hyperopic astigmatism and perfect visual acuteness of both eyes with accurate correcting lenses. Without these lenses she is lefteyed, but with them right-eyed. The higher defect in the right eye without proper ametropic correction had evidently but recently turned the dominance over to the left eye. Just in time, therefore, it has been retransferred to the right.

M. K. has now, at 22, R. + cyl. 1.00 ax. 75° = 20/20 +, L. + cyl. 1.87 ax. 105° = 20/20. She was naturally lefthanded, but was forced to write with right hand. She sews, uses knife at table, throws ball, etc., with her left hand. She can still write as well but not quite so fast with the left as with right. She sometimes misses her mouth in

eating, plunging the food or fork against the lips or cheek. She puts away the thing she wished to keep, and *vice versa*. She has been much laughed at all her life for doing such awkward and unintended things. When talking she often "gets ahead of herself." She often blunders, in this way, for instance: "What is the capital of Paris?" In playing the piano the left hand follows the right as a "trailer." She has had a long, tragical life of suffering, migraine, spinal curvature, vomiting, etc., etc.

M. M. was a lefthanded child compelled to write with her right hand. She tried to learn to play the piano, but could not do it. She often calls well-known persons by the wrong name, misnames objects, etc., and instantly knows she is wrong. She has spinal curvature, subnormal accommodation, and has had a life history of sickheadaches, dizziness, confusion, lack of power of concentration, etc.

E. A. O. was a lefthanded child, compelled to write with the right. She gets confused in speech, mixes her words, etc. She is righteyed when holding the test-instrument in the right hand, but lefteyed when holding it in the left hand. The error of refraction is the same in both eyes.

R. E. T. was a lefthanded child, trained to write with the right hand. He has been a lifelong sufferer, sickheadaches, insomnia, dizziness, unsteadiness, chorea, "faint spells," swoonings and fallings, etc. He stutters badly, this symptom beginning in youth. He is now entirely relieved of all these symptoms, except stuttering. He is still a righthanded writer, but is lefteyed.

E. L., at 12 years of age, is lefthanded, but righteyed. She now has over two diopters more of unsymmetric hyperopic astigmatism in the left eye than in the right, and from lack of proper glasses this left eye has an incapacitating amblyopia. Correction of the ametropia in the left has in a few months doubled the visual acuteness.

F. O., aged 20; his right eye was injured by a blow with a hoe, ten years ago, so that at present it has an error of about 4 diopters of compound myopic astigmatism, with 20/40 visual acuity with accurate correcting lenses. He is righthanded, but has been compelled by the injury to become consciously lefteyed, shooting from the left shoulder, awkwardly, slowly, and with conscious difficulty, and, of course, aiming with the left eye. He plays billiards lefthandedly with the same trouble. He is practically blind with the right eye at near range.

W. R. O., when first tested without a mydriatic or any correcting lenses, was righthanded and lefteyed. After mydriasis, under correcting lenses, he was as clearly and persistently righteyed, with better acuteness of vision also in the right. He has always been righthanded. The anomalous lefteye dominance has therefore been reversed by correction of ametropia.

H. J. H. is righthanded, and remains righteyed despite the higher astigmatism of the right eye, measured as follows:

R. + cyl. 1.75 ax. 180° = 20/20.
L. + sph. 0.37 + cyl. 0.75 ax. 15° = 20/20.

This is probably because the axis of the astigmatism in the left is oblique.

C. N. K. was lefthanded as a child, but was compelled to become a righthanded writer. She still remains lefteyed, although her error of refraction is greater in this eye than in the other.

M. A. H. is lefthanded, but was forced to write with the right hand as a child. He is now righteyed. His present ametropia, at the age of 52, does not account for his righteyedness, as, although his astigmatism is unsymmetrical, it is of too low a degree, and too near alike in the two eyes to explain the reversal. Originally, therefore, his defect must have been greater in the right eye, and under the influence of severe eyestrain (with local ocular, not systemic reflexes), the ametropia became about equal in the two eyes, and thus permitted the transfer of dominance to the right eye.

H. D. A. is lefthanded, forced as a child to write with the right hand, and is now righteyed. The higher ametropia in the left facilitated the transfer of dominance to the right eye. Another patient (S. L.) had the same condition, and the extremely high hyperopia of the left has rendered the eye almost blind because of amblyopia from lack of correcting lenses.

C. H. E. is righthanded in writing, using a screwdriver, sighting a gun (from right shoulder), testing levels, violin-playing; but he is lefthanded in eating, hammering, sawing, planeing, microscopy, and billiard-playing. He is certain that, as a child, he was not trained to be a righthanded writer, but always unconsciously chose the right hand for writing. Either without a mydriatic, or with it, he is, by all tests, clearly lefteyed, and whether with or without ametropic correction. His visual acuteness is sharper with the left eye than with the right, either with or without the mydriatic, and whether with ametropic correction or not. His present ametropia does not explain the choice of the dextral or the sinistral eye for expert tasks. As a child he was, of course, righteyed. He may have some time temporarily lost the superior acuteness of the right eye from ametropic changes, or passing inflammation, etc., and subsequently regained it. More probably, there has some time been some injury to one arm that made the other arm and hand do certain tasks more easily, and these were consequently transferred. Even a sharply localized cerebral injury may have been the cause of the replacement of one hand by the other for certain tasks.

N. S. C., 18 years old, always righthanded, was struck in the right eye three and one-half years ago by a stone. The retina was injured by *contrecoup*, reducing the central acuteness to 20/200, after correction of his compound myopic astigmatism. After wearing correct spectacles for a year this eye has now 20/70 visual acuteness. He has, of course, become a lefteyed man since the accident, and has slowly learned by experience that he must shoot from the left shoulder, that he must play billiards lefthandedly, and to throw a ball with the greatest accuracy he must use the left hand. He has practically become a lefthanded man in the few years since the accident. His error of refraction at present is:

R. — sph. 0.62 — cyl. 1.25 ax. 90° = 20/70.
L. — sph. 0.62 — cyl. 0.75 ax. 75° = 20/20 +

W. A. F. is lefteyed by all tests, and yet he is normally righthanded and has always been so. His static error of refraction is:

R. + sph. 0.87 + cyl. 0.75 ax 80° = 20/20 +
L. + sph. 0.62 + cyl. 0.62 ax. 95° = 20/20 +

L. M. A. is lefteyed and righthanded. The peculiarity of the right axis of astigmatism explains the anomaly. She was wearing simple spherical

lenses (+ sph. 0.50) alike in the two eyes, when her real error is as follows:

R. + cyl. 0.50 ax. 25° = 20/20 +
L. + cyl. 0.62 ax. 180° = 20/20 +

J. S. B. is righthanded but lefteyed, because of two reasons: She has been wearing, *for reading only*, B. E. + sph. 1.50 + cyl. 0.50 ax. 180°, which aided in excluding the right eye from use, and because it did not aid it in overcoming the following defect:

Distance.

R. + sph. 0.37 + cyl. 1.50 ax. 180° = 20/20
L. — sph. 0.25 + cyl. 0.37 ax. 165° = 20/20

R. + sph. 2.50 & cyl.
L. + sph. 1.75 & cyl. } Near. In bifocals.

To order a presbyope with such ametropia as this to go without distant glasses altogether, and to miss the presbyopic diagnosis of the right eye by two diopters was more than enough to bring about the unfortunate result.

L. B. is righthanded and lefteyed, because the extremely high degree of malcorrected astigmatism in the right eye threw it out of use.

S. R. G., although naturally a lefthanded writer, was, as a child, compelled to write with the right hand, and, with the exception of billiards, is now habitually righthanded. Without a mydriatic, or correcting lenses, he has about 20/40 visual acuteness. His postmydriatic ametropic error is:

R. + sph. 0.37 + cyl. 2.62 ax. 95° = 20/20 +
L. + sph. 0.50 + cyl. 2.50 ax. 95° = 20/20 +

G. H. is a common laborer, righthanded for everything, but lefteyed. This was caused by the existence of an enormously high compound hyperopic astigmatism, for which he had been wearing atrocious glasses which threw his right eye out of use. With + sph. 5.25 + cyl. 3.50 ax. 8° this eye was given nearly perfect vision. He may in time regain his righteyedness.

M. A. G. is righthanded for all tasks, but lefteyed. He has never had the use of his right eye, especially since wearing such glasses as these:

R. — cyl. 1.00 ax. 90°
L. — cyl. 0.50 ax. 180°

With the following correction he gets back a second eye, has binocular fusion and may possibly regain righteyedness:

R. — sph. 8.00 — cyl. 1.00 ax. 45° = 20/40 +
L. — sph. 0.12 — cyl. 0.62 ax. 180° = 20/20 +

M. K. C., 14 years old, was early compelled to use her right hand for writing, when she was naturally lefthanded. The ametropic defect being almost exactly the same in the two eyes, "Nature" evidently found it also possible to reverse the ocular dominance in a naturally lefthanded child, and righteyedness was established.

R. L. C. has developed one or two diopters of mixed astigmatism in the right eye above that of the left, and this has given the left the dominance, while he remains righthanded.

R. D. E. is righthanded and lefteyed. Her error of refraction (at 35) is:

R. + sph. 2.25 — cyl. 5.50 ax. 15° = 20/25
L. + sph. 0.75 — cyl. 3.50 ax. 175° = 20/20 +

M. G. F. is righthanded but lefteyed, because a choroiditis (of nephritic causation) has reduced the acuteness of the right eye to less than one-half the normal.

H. J. F. The axes of his astigmatism are 65° in the right and 90° in the left. Correct spectacles would have doubtless preserved his righteyedness. He is now righthanded and lefteyed.

J. G. B., a woman of 41, became lefteyed in childhood and youth because of several diopters of uncorrected hyperopic unsymmetric astigmatism, higher in the right eye than in the left. The glasses which she has worn during the last twelve years have increased instead of lessened the handicap of the right eye.

H. J. C. is lefteyed because of five diopters of uncorrected hyperopic astigmatism, with resultant amblyopia, but he is so decidedly righthanded that he tried to shoot, in hunting, from the right shoulder and sighting with the left eye; he had to give it up because the "kick" of the gun hurt his face so much.

A. F. C., while righthanded, is lefteyed, because, since the establishment of righthandedness, a high (uncorrected) myopic astigmatism has developed in the right eye at an oblique axis, which has thrown it out of dominance.

G. L. E., when a boy, fell in lime, and the resultant inflammation of the right eye ended in a leucomatous cornea, one-half normal visual acuteness, and the transfer of dominance to the left eye. He still remains righthanded. The accommodation in the right eye is paralyzed, but that of the left eye is normal.

H. G. was a lefthanded child, trained to use the right for writing, and is now lefthanded for all other acts. He shoots from the left shouder, aims with the left eye, plays ball lefthandedly, etc. He now writes lefthanded mirror-writing with ease, unconsciously, and at the first trial. His refraction error is a moderately high compound hyperopic astigmatism, the astigmatism higher in the right, with good visual acuity of each eye.

The only patient we have ever had who in the least approximated "ambidextrality," is a young woman who, lefthanded as a child, was early forced to write with the right hand, and to do a small number of other things with this hand which she had preferred to do with the left. She can now, actually, write equally well with either hand, but preserves her natural lefthandedness in the performance of several other tasks.

The explanation of this anomalous condition, however, is evident: She was and remains a person of wonderful plasticity and adaptability of character and of physiology; and she was precocious in intellectual development and exceptional in acquirement; but more conditioning and illuminative still is the fact that the two eyes have the same amount and kind of ametropia, the slightest possible, and the least handicapping we have ever found, with equal acuteness of vision, etc. The probably unique result is that the girl is righteyed when using her right hand or with the attention directed to the work of this hand, and just as clearly lefteyed when attention is directed to the task of the left hand. Even in holding the instrument for testing dominance in the right hand she is as decidedly righteyed as she is lefteyed when holding the instrument in the left hand. It is safe to say that such a nearly perfect pair of eyes does not exist in the multitudes of pitiful martyrs whom barbaric prejudice has tried to make into sadly unsuccessful "ambidextrals."

THE NOGUCHI METHOD OF SERUM DIAGNOSIS OF SYPHILIS; ITS PRACTICAL VALUE.*

By DAISY M. ORLEMAN ROBINSON, M.S., M.D.

NEW YORK.

INSTRUCTOR IN DERMATOLOGY, N. Y. POLYCLINIC MEDICAL SCHOOL AND HOSPITAL, DERMATOLOGIST, NORTHWESTERN DISPENSARY.

Syphilis can be detected to-day by means of the laboratory method discovered by Wassermann, Neisser, and Bruck, without clinical observation of the patient. The technique of the reaction, which is based upon the principles of the Bordet-Gengou phenomenon of complement-fixation, is very complicated and calls for much skill to perform it properly. It requires a competent laboratory worker and a fully equipped laboratory, because of the difficulty in preparing the reagents necessary for the test and in their preservation, and the necessity of standardizing and adjusting the dosage of each required reagent—namely, amboceptor, complement, antigen, blood corpuscles, and patient's serum.

These five reagents or factors should be employed in definite quantities for the accomplishment of which a thorough serological knowledge is demanded. It is only necessary at present to indicate that the method originally described by Wassermann was available to a limited number of workers only, and it is not surprising that various investigators attempted to simplify the technique, so that a larger group of workers might avail themselves of the test. It is my purpose in the present article to relate my experience with one of the modifications recently advanced, which appears to be more practical than the original, and at the same time reliable and accurate.

Before describing this method, it may not be superfluous to review, briefly, certain other modifications, in order to show why this particular one was followed.

There are, generally speaking, two principal groups of methods by which the complement-fixation test is carried out, the essential difference being in the use of foreign or human blood corpuscles as a hemolytic indicator.

Among the first group, in which foreign corpuscles are used, may be mentioned the original method of Wassermann and its modifications by various investigators. For example, Bauer, Hecht, and Stern use sheep's corpuscles, as in the original method, while Boas uses the corpuscles of a goat, Browning the corpuscles of an ox, Detre of a horse, Foix of a rabbit, and Tschernogubow of a guinea-pig. These methods, considered from a practical and theoretical standpoint of use, may again be subdivided, according to the source of complement and amboceptor that are to constitute a part of the hemolytic system, together with the foreign blood corpuscles. Thus, some modifications rely upon the natural hemolytic amboceptor preexisting in the serum of the patient under examination against the foreign corpuscles chosen for the hemolytic indicator. Speaking more specifically, the method of Bauer or Hecht or Foix or Tschernogubow utilizes the natural amboceptor for the corpuscles of a sheep, rabbit, or guinea-pig, respectively. Some of the modifications rely entirely upon the natural hemolytic property of the serum of a given patient utilizing at the same time the complement and the amboceptor; such is the case in the modifications proposed by Hecht, Foix, or Tschernogubow. A slight deviation from the last-mentioned ones is to be noticed in that of Stern, who adds a certain amount of an immune hemolytic amboceptor (for sheep's corpuscles) in addition to the natural amboceptor and complement of the serum of a patient, to render the test possible in such cases where the natural amboceptor may be absent. When carefully considered, one will discover that in order to gain in more or less simplification in these modifications there is a singular lack of the quantitative aspect of the subject. They seem to disregard the necessity of employing definite amounts of four out of five factors, while attempting to discover the amount of the remaining one. A simple equation would convince one that in finding out one unknown factor from a total sum of 5, one should know the amounts of 4 factors, definitely. It is evident that in the methods in which native hemolysins, no matter whether the complement or amboceptor, or both, are used, the determination of these factors would be impracticable, and, indeed, are not demanded by those who advance these methods. Now, the amount of natural hemolysins in human blood serum is variable, and often one (amboceptor) of the two factors is absent or present in excess. The above show the theoretical defects in these modifications.

Practically considered, we must first mention that the examination by these modifications must be done within 24 hours after the blood is drawn from the patient, since the complement becomes gradually weakened after the lapse of 48 hours, and deteriorates rapidly after a few days. A specimen that has been kept at room temperature for 24 hours is unsuitable for examination in any of the above modifications.

Regarding antigen—recently an alcoholic extract of normal or syphilitic tissue was proven to be as reliable as the aqueous extract originally described by Wassermann. And yet certain discrepancies existed as to the reliability of the alcoholic extracts. Why should they act in the same way, and why, then, may they not act differently?

It is known that extraction of certain tissues by means of alcohol gives rise to various results, as, for instance, the amount of autolysis an organ undergoes before extraction—the proportion of alcohol to the tissue—the temperature—length of time—and the varieties of the tissue, all may contribute to this difference. One organ may contain a group of fatty substances which will counteract the effect of other sets of lipoid substances and obscure the antigenic property of the latter. Therefore, it is inadvisable to use the unfractionated alcoholic extracts for any comparative study, because none of these conditions can be controlled. In the scrutiny of the methods, it will be seen that none of them can fulfill these essential requirements as well as Noguchi's.

Upon critical consideration of this method, it will be observed that each reagent can be used in a separate case, and is capable of being titrated before use; the complement is from a guinea-pig; the patient's serum can be used not only in an active state, but also after the lapse of an indefinite period of time, as well as after inactivation. This condition is more advantageous than the other methods in that in them the serum must be used either in an active state (before the rapid deterioration of its own complement) or in an inactivated state.

From the standpoint of the convenience of the

*Read at the Forty-third Annual Meeting of the Canadian Medical Association in Toronto, June, 1910.

method, that of Noguchi offers the use of dried reagents to those desiring to avail themselves of the simplification. This at first may appear to be more of a commercial factor, but the principle is fundamentally different. The drying of the amboceptor renders it invulnerable to bacteriolytic decomposition. It retains its activity much longer than in the liquid form, not only when preserved in a refrigerator, but likewise when exposed to any climate. Liquid amboceptor deteriorates rapidly in transportation through mechanical agitation, from which disadvantage the dried preparation is free. It is easily titrable, adapted to quantitative work if desired. As for antigen, Noguchi eliminates various disturbing constituents of whole alcoholic extracts by a subsequent fractionation with acetone, obtaining the insoluble portion as antigen. This fractionation makes the extract more uniform in action, irrespective of the source, and offers the advantage of being durable. Besides, the papers can be impregnated with a concentrated etheral solution of this fraction, and in this state it keeps for a very long time—possibly a year. Noguchi had one preparation which showed no appreciable deterioration at the end of a year. An alcoholic solution of this fraction can be made, from which a definite quantity is measured and emulsified in a physiological salt solution before use.

As will be shown later, Noguchi makes a distinction between the use of an acetone insoluble fraction of lipoids and an entire alcoholic extract. The former, which is a method of his own, can be used for both the active and the inactivated serum, while the latter is not recommended for active serum. The method which I employ is as follows:

Complement.—The fresh serum of a guinea-pig, in the strength of two units, usually 0.1 cc. of a 4 per cent. dilution of serum for each tube. It is best to use the serum after twenty-four hours' contact with the clot kept on ice, and, if possible, to mix more than two sera, in order to obtain uniform results, because guinea-pig sera, while fresh and normally reactivating for the amboceptor, may sometimes show a variation in regard to its fixation quality. Some sera may be highly insensitive to fixation, thus giving a negative reaction in a syphilitic case. The dried complement offers no advantage, and is difficult to prepare.

Amboceptor.—The serum is obtained from rabbits sufficiently immunized with washed human corpuscles. When it is dried on filtered paper it retains its activity for a long period of time, and this dried amboceptor offers no possibility of being spoiled by bacteria or by exposure to a tropical temperature, as in the case of liquid serum. Titration of a dried amboceptor paper is just as simple as the liquid amboceptor, and can be carried out with equal precision. The liquid amboceptor is equally as convenient as the paper form for those who are using a considerable amount of amboceptor and who have a good refrigerator. Another advantage of the paper form is the omission of strict asepsis in collecting the immune serum from rabbits, because the serum can be dried on paper before bacterial infection takes place. Before impregnation, the serum should be inactivated. For a fixation test, two units for each tube are used.

Corpuscle Suspension.—One cubic centimeter of a 1 per cent. suspension of washed human corpuscles in 0.9 per cent. salt solution is the standard. The blood should be obtained from non-syphilitic individuals. It is first defibrinated, or collected in a sodium citrate solution and washed by centrifugalization, and then made into suspension. The corpuscles of a given patient may be utilized in testing the same serum if the specimen is fresh (24 hours). The collected blood is allowed to coagulate, the serum is then slightly mixed with corpuscles by stirring the clot gently with a capillary pipette. The amount of corpuscles to be stirred should be sufficient in that one capillary drop of the serum will make approximately a 1 per cent suspension when mixed with 1 cc. of a 0.9 per cent. salt solution. If one intends to employ inactivated serum, the washed corpuscles of a non-syphilitic person are employed. One cubic centimeter of defibrinated blood is sufficient to perform about 50 examinations. Human corpuscles are sometimes good for about three days, if kept in a refrigerator. When the supernatant fluid of this suspension becomes tinged with hemoglobin, it cannot be utilized.

Patient's Serum.—This can be employed in two different ways, namely, unheated (active), and in the inactivated state. Active and inactivated sera give the same results when properly used. One of the most essential conditions to obtain reliable results with active sera is to use antigen prepared by the Noguchi method, in which pure lipoids (acetone insoluble-fraction) of normal tissues is used, and the indiscriminate use of all so-called syphilitic antigen preparations, such as aqueous or alcoholic extracts of syphilitic liver, should be avoided. Noguchi's recent experimental studies show that active sera have often a peculiar property of binding guinea pig's complement when mixed with various proteins, such as albumoses, peptone, nucleoproteins, certain cleavage products of proteins, glycogen—while such a false fixation phenomenon does not occur when mixed with pure lipoids (acetone-insoluble fraction). Inactivation removes this non-specific "proteotropic" fixation property from such sera. This explains why one should not use certain other syphilitic antigens in combination with active human sera, and accounts for the interesting observation of one author who employed alcoholic extract of the liver of a dog or of a syphilitic fetus. But this restriction in the antigen preparations does not affect the practicability of the Noguchi system.

These aqueous or alcoholic extracts of syphilitic fetus tissue can readily be abandoned, since they are noted for their variableness, instability, and difficulty of preparation, unless used with inactivated sera. Inactive as well as active sera can be used with equal reliability. The use of active sera in a test calls for less amount of blood. Moreover, the native corpuscles of the specimen, as already mentioned, can be utilized, for the hemolytic indicator. There is no necessity of inactivation. Inactivation, however, is sometimes necessary when human sera becomes old—about one week—in which case it often becomes anticomplementary, which must be corrected by means of inactivation. It is extremely rare that human sera not over forty-eight hours old contains an anticomplementary property. The quantities used in the test differ according to whether or not the sera is inactivated. With active sera 0.02 cc., and with inactivated, 0.08 cc. is used; with cerebrospinal fluid, 0.2 cc., while for ascitic fluid, 0.1 cc. is advised. In testing serum, a capillary pipette that measured about 0.02 cc. in one drop is employed, while in special quantitative work regular graduated pipettes are used. The capillary pipette is sufficiently accurate for general routine work.

Antigen.—For active sera, only acetone-insoluble

fraction of pure tissue lipoids should be used. Extract one part of minced tissue (liver, heart, kidney), with nine parts of 95 per cent. alcohol for several days at 37° C. Filter the extract through filter paper. The filtrate is evaporated in a flat dish by the aid of an air current. The sticky mass is then extracted with ether, and this ether solution is filtered through paper. The filtrate is condensed to a small volume by evaporation. Lastly, it is mixed with acetone (about 10 volumes). A precipitate will then be formed. The precipitate is collected and used as antigen. The modes of its use are as follows: First, to impregnate filter paper with concentrated ether solution of this substance. The impregnated paper is afterwards titrated to determine the dimension necessary for the test. Secondly, the other, which is in liquid form, is prepared by dissolving 0.3 gram of this substance in about 4 cc. of ether, and then mixing with 100 cc. of a 0.9 per cent. salt solution. Usually 0.1 cc. to 0.2 cc. is sufficient. Thirdly the substance may be dissolved in methyl alcohol (0.75 gram in 50 cc. of methyl alcohol). One part of this solution is mixed with 4 parts of salt solution (0.9 per cent.) and 0.1 cc. of this emulsion is used for each test. The original solution is retained for further use because it is advisable to make this emulsion freshly before use.

Regardless of the mode employed, the antigen preparation should be titrated before its strength is determined, and the quantities mentioned refer merely to the average preparation, and cannot be accepted as a standard. For transportation in ready form, the paper is absolutely the best. Oxidation seems to affect both the paper and the liquid forms.

For inactivated sera, aqueous, alcoholic, and pure lipoids (acetone-insoluble) may be used. The quantity of antigen must of course be determined with each preparation. Acetone-insoluble fraction of tissue lipoids, in liquid or paper form, is preferred on account of uniformity of action.

In making the test, do not under any circumstances omit the necessary controls: Postive syphilitic serum, normal serum, and hemolytic system, each set with and without antigen. Noguchi usually adds washed corpuscles to the mixture from the beginning, but they may be added after the first incubation at the same time as the amboceptor. In the latter case, the factors for the first incubation (patient's serum, complement with and without antigen) are in 1 cc. of 0.9 per cent. salt solution instead of a 1 per cent. suspension of washed human corpuscles, as in the first procedure. At the end of incubation 0.1 cc. of a 10 per cent. suspension of washed human corpuscles is added, thus rendering the entire mixture approximately a 1 per cent. corpuscle suspension. For routine work, a concentrated suspension of washed human corpuscles is prepared, so as to make one drop from a capillary pipette (made when needed) 1 per cent. suspension in 1 cc. As long as every tube of the entire series receives a uniform quantity of corpuscles, a slight variation in percentage, such as 0.1 per cent. more or less than the prescribed 1 per cent., cannot alter the test. The more vital factors, other than corpuscles, are beyond perfect control at best. First of all, complement of various guinea-pigs is variable in fixability. The equally vital factor, the amboceptor, has been made controllable only in the Noguchi system.

The importance of this unknown quantity of amboceptor can now be appreciated in the complement fixation test. A serologist who uses a heterohemolytic system may measure very carefully 1 c.c. of a 5 per cent. suspension of washed sheep's corpuscles with all technical care—but does he realize that this is actually the same as measuring blindly any quantity from that suspension? In making up a hemolytic system, units of complement, amboceptor, and corpuscles in their relative proportions must be employed. Supposing the quantity of amboceptor is increased by 10 times the unit without changing the quantities of the other two factors (complement and corpuscles) what will be the result? By this partial change, changes in the other two units are produced. The latter do not longer stand to one another as units, since a condition is produced similar to that which will arise from an increase of complement or from a reduction of the quantity of corpuscles, without changing the quantity of amboceptor. Thus, the serologist is working with the conditions comparable in results with those arising from the use of unknown, arbitrary, highly variable quantities of corpuscles, and a condition may be confronted equivalent to the use of one unit, or that of a fraction of the unit. This uncontrollable condition is enhanced by another fact—that there may not be a single set in the entire series, say of 20 tests, the conditions of which can be compared with each other.

The contents of the various test tubes are indicated in the following table:

Rear Tubes

Unknown Serum	Positive Control	Negative Control	Hemolytic Cont'l
Patient's serum (active 0.02 cc., inactive 0.08 cc.)	Positive syphilitic serum (active 0.02 cc., inactive 0.08 cc.)	Normal serum (active 0.02 cc., inactive 0.08 cc.)	No serum (hemolytic system).
Complement (40 per cent) 0.1 cc.	Complement (40 per cent) 0.1 cc.	Complement (40 per cent) 0.1 cc.	Complement (40 per cent) 0.1 cc.
Corpuscle suspension (1 per cent) 1 cc.	Corpuscle suspension (1 per cent) 1 cc.	Corpuscle suspension (1 per cent) 1 cc.	Corpuscle suspension (1 per cent) 1 cc.

Front Tubes

Same as above with antigen.	Same as above with antigen	Same as above with antigen.	Same as above with antigen

(1) First incubation for one hour at 37 C. (2) Addition of 2 units with antihuman amboceptor. (3) Second incubation for 2 hours at 37 C., then at room temperature. (Reading the reaction after several hours. With inactivated sera the results can be taken immediately after second incubation.)

I have just completed, by the above method, the examination of 410 cases, including various forms of skin diseases, of patients at my clinics. The results of 180 cases of syphilitics agree with those of other investigators:

	No. of cases.	Positive	Percentage
Primary syphilis	29	25	86
Secondary syphilis	48	45	93
Tertiary syphilis	60	48	80
Latent syphilis	53	23	69.6
Hereditary syphilis	10	10	100.

It will be noted that the highest percentage was obtained in the second stage, the negative cases being those which were under treatment. The positive percentage of primary syphilis is not as high as in the secondary stage: the negative reactions were obtained too early in the disease. Hereditary syphilis invariably gave a positive reaction.

The remaining cases—236 non-syphilitic—gave negative results, as follows:

Acne Vulgaris, 18; Acne Rosacea, 6; Alopecia Areata, 10; Dermatitis Herpetiformis, 3; Dermatitis Traumatica, 6; Dermatitis Venenata, 4; Eczema, 25; Epithelioma, 30; Erythema Multiforme, 5; Erysipelas, 3; Erysipeloid, 3; Favus, 2; Scabies, 6;

Herpes Zoster, 10; Hydrocystoma, 3; Ichthyosis, 4; Impetigo Contagiosa, 14; Lichen Planus, 10; Lichen Rubra Pilaris, 1; Lupus Erythematosus, 10; Lupis Vulgaris, 4; Mulluscum Contagiosum, 3; Nævus Pigmentosus, 3; Pityriasis Rosea, 4; Pityriasis Versicolor, 3; Psoriasis, 15; Purpura, 5; Trichopytosis, 10; Tiberculosis Cutis, 3; Urticaria, 13.

Conclusion: The object in making the above test was to determine whether the reaction is present in diseases other than syphilis, when tested by Noguchi's method. Among the cases thus examined, it will be noted that a positive reaction was obtained only in syphilis. In regard to the positive results in certain cases of leprosy, yaws, etc., this modification is similar to the Wassermann method. The investigations of Boas, Sachs, and others show that the use of unheated serum causes nonspecific complement-fixation in some nonsyphilitic cases, while this does not occur when one employs inactivated serum. But this difficulty can be avoided by adopting the method of preparation of antigen described by Noguchi, as already stated. The recent reports of some investigators, to the effect that the use of active serum in Noguchi's system sometimes causes positive reaction in nonspecific cases, can be attributed to their indiscriminate use of antigen. These authors almost invariably used unfractionated whole alcoholic extract of macerated liver, which, of course, is rich in undesirable proteins and glycogens.

From my experience I feel justified in stating that the Noguchi method is simple, delicate, and gives reliable results.

SOME REMARKS ON DEAF-MUTISM.*

By E. W. SCRIPTURE, Ph.D. (Leipzig), M.D. (Munich),

NEW YORK.

ASSOCIATE IN PSYCHIATRY, COLUMBIA UNIVERSITY; VISITING PHYSICIAN FOR SPEECH DEFECTS TO RANDALL'S ISLAND.

By deaf-mutism we understand a condition of deafness, either total or partial, followed by failure to learn to speak or by loss of speech already learned. The inability to speak is the result of the deafness and not of any defect in the speech mechanism. Congenital deaf-mutism is attributed mainly to heredity and consanguinity, also to alcoholism, syphilis, difference in the ages of the parents, and to diseases of pregnancy. Acquired deaf-mutism is due chiefly to meningitis. It also frequently follows scarlet fever. Other diseases, like measles, diphtheria, typhoid fever, mumps, influenza, etc., sometimes produce it.

What is to be done with the deaf mutes? The one thing of supreme importance is to teach them to speak. Mental awakening is the first step in the training. The mind of the deaf-mute is often in a backward condition because he does not fit with his surroundings. The exercises include mimetic movements, following the teacher in running, walking, sitting, blowing feather, etc., also games (such as catching ball, tossing beanbag, hiding thimble, etc.). Thus the child's attention, observation, imitation, and imitative construction are developed.

The speech development proceeds along lines that will now be illustrated in an abbreviated form by exercises with a group of three deaf mutes. Of these, two were born deaf. The other one became totally deaf at the age of three years; through lack of use of the vocal organs he lost what speech he had; he has attended a school for deaf-mutes where the sign language was used. The following exercises are typical of those used in the best schools:

1. Breathing through the nose and mouth are first taught. The teacher breathes through the nose on a slate or a mirror and shows the two moist

spots; the child learns to imitate this. The mouth breathing produces one spot.

2. The low position of the tongue is necessary for proper speech. It is taught by showing the position and using the mirror, and by a breath exercise. This latter rests upon the fact that the child cannot produce a good-sized spot on the slate unless he keeps his tongue down.

3. Tongue gymnastics are next used to limber up and train the muscles which have never received the proper development. The tongue is protruded, retracted, moved to each side, turned up, etc.

4. Tongue training preparatory to various consonant sounds is introduced. For example, the child is taught to put the tip of the tongue against the teeth; this gets him ready for the letter "t." He learns to draw it back and close it against the hard palate, thus getting ready for "k."

5. Vibration of the vocal cords is taught by feeling. The pupil puts his hand on the teacher's chest and also on his own. He thus learns to make a tone. He learns to raise and lower the voice, and by careful drill is able to make a fairly good tone.

6. The physiological alphabet consists of a set of diagrams giving the typical positions of the tongue and lips for the chief sounds of the language. Here for example are the diagrams for "t" and "k." The child learns these diagrams just as we learn the alphabet, so that he can both make the sound and write the letter or group of letters for it.

7. Combinations of consonants and vowels are now read at sight. Through these combinations words and sentences are developed.

8. Lip-reading of words and sentences is taught by having the patient watch the teacher's lips while she distinctly enunciates some word. Thus he learns to pick up objects off a table, to point out parts of the body, to obey commands, etc.

When deafness is acquired after the person has

learned to speak, the teaching of lip reading should begin at once. The voice then retains its natural character and the person can go right along with his education. Here are two boys who became deaf at the ages of thirteen and eight, respectively; they are now seventeen and twelve. They understand nearly everything that is said to them and are able to talk fluently.

*Address before the New York County Medical Society, February 28, 1910.

The unnatural character of the voice which the congenital deaf-mute acquires is the one drawback; still it is immensely better to be able to understand well and to speak fairly well than not to be able to do either. There is, however, a series of methods recently developed by the science of experimental phonetics by which the niceties of pronunciation are studied and taught. Foreigners are enabled by these methods to acquire a correctness of pronunciation otherwise impossible. The person is taught exactly how to place his tongue, to produce his nasal breathing, to regulate the length and intensity of his vowels and consonants. Here the work of special private instruction may begin for those deaf-mutes who wish more than the schools can offer.

In closing, I wish to report a curious case of sensory aphasia coming on at seven years of age after scarlet fever. The man's hearing is perfect but he has no understanding for the words he hears. His intellectual condition is excellent. He did not go to school and never learned to read and write. Apparently he has motor aphasia. Some questions he understands, if he can see the lips of the speaker; he has thus of his own accord begun to learn lip reading. It is my belief that he has no motor aphasia, but that he simply never learned to speak. He should, therefore, be taught lip reading just as if he were a deaf-mute.

87 Madison Avenue.

FURTHER OBSERVATIONS ON THE PATHOLOGY OF JOINT TUBERCULOSIS AND PRACTICAL DEDUCTIONS THEREFROM.*

By LEONARD W. ELY, M.D.,

DENVER, COL.

One year ago it was our privilege to read a preliminary paper on the pathology of joint tuberculosis before this association, giving the results of our study of some forty-three joints.[1] We have continued the work, and have added to our collection nineteen more specimens, bringing our total up to sixty-two. We have submitted the new joints to a thorough laboratory examination, and have also reexamined the old joints, cutting and staining many new sections in a search for possible errors in our former conclusions. The subject broadens as one pursues it, and in the limited time allowed to us to-day, we shall endeavor to bring out some of the more important points, sacrificing fullness of argument to brevity, and beginning by a statement of the definition of the term "joint tuberculosis." It is the reaction of the tissues in and about a joint to the presence of tubercle bacilli and of their toxins.

There are four essential elements of a joint, viz., bone, cartilage, ligament, and synovial membrane. These are all connective tissue structures and are formed from the mesoblast. Virchow's original definition of a tubercle limited it in its occurrence to connective tissue, but ordinary fibrous connective tissue is seldom, if ever, involved in tuberculous disease. There must be some peculiar cellular element in addition.

We find tuberculosis in those connective tissue structures which contain epithelial, epitheloid, and lymphoid cells. As a matter of fact, ligaments and cartilage are never involved either early or late. They suffer purely from interference with their nutrition. The bone structure itself, the trabecula, also escapes, and also suffers by interference with its nutrition. The disease appears in the marrow and spreads in the marrow. The term "bone tuberculosis" is confusing. It would be much better to say tuberculous myelitis. (Myelitis as applied to the spinal cord is a misnomer.) Cartilage is fibrous connective tissue plus a cement substance, and bone is fibrous connective tissue plus lime salts. In both the fibrous structure can be seen in their degeneration. The synovial membrane is lined in places by epithelioid cells, especially the portions of it forming the fringes, and the "synovial villi" consist largely of small round cells with granular protoplasm.[2] The synovial membrane therefore answers in structure to the conditions we usually find in the tissues of the body subject to tuberculosis. As to the marrow, that in the shafts is largely fat, that in the cancellous ends of the long bones and in the short and flat bones, the sternum, ribs, cranial diploe and vertebræ is of the red or cellular variety, with various kinds of cells. Where this marrow occurs in bone we find tuberculous disease, where it does not, we do not find it. Hence the occurrence of tuberculous disease in the epiphyses and not in the shafts, heretofore never satisfactorily explained. Hence also the frequency of the disease in children. Their bones contain more red marrow. Study of our specimens teaches us that only two elements of a joint, then, are subject to tuberculosis, the synovial membrane and the red marrow in the bone. This is important and will be referred to later.

As to primary involvement we reaffirm our opinion, stated last year, that it may be either of bone marrow or of the synovia. Our arguments have already been given. We have seen several specimens during the past year that confirm this view. We quote one case—a knee joint in a patient of twenty-four years, who had suffered moderate pain and disability in his knee for seven years. This joint contained fluid, and was somewhat limited in its flexion. There was no circumarticular swelling, no angular deformity, and little if any atrophy. At operation the cartilages appeared perfectly smooth, and the synovial membrane appeared normal except for the presence of numerous pedunculated bodies hanging from it. Some of these were cut off, the joint was sewn up, and plaster-of-Paris was applied. The diagnosis was changed to chronic inflammation, but a laboratory examination of the tissue removed showed tuberculosis. Some weeks later the plaster was removed, and the joint grew rapidly worse. Two months after the first operation a resection was done. The cartilages were found extensively eroded at their sides and the synovial membrane badly diseased; in its substance could be felt hard bodies the size of a small bean, which on section proved to be collections of cheesy material, and some of the enlarged villi contained areas of necrosis. Microscopical examination showed extensive tuberculosis of the synovial membrane, but no bony involvement. This case also exemplifies the aggravation of the disease in a tuberculous joint by a partial operation. Our opinion is that primary disease is about equally common in the synovia and in the bone marrow, at least in adults, from whom our specimens were almost exclusively taken.

The percentage of errors in diagnosis found last year (33⅓) was so disquieting, that we submitted

*Read at the annual meeting of the American Orthopædic Association, Washington, May, 1910.

the specimens to a second thorough examination, cutting many new slides from different parts of the joint. No material change resulted. The percentage of error in the sixty specimens in which the clinical diagnosis was given is exactly thirty-five. Either a pathological examination is unreliable or else our diagnostic methods need improving.

We consider that the erosion of the cartilage by the "tuberculous pannus," on which König laid such stress, is of slight importance. The damage to the cartilage is done from beneath. "Layers of fibrin" on its surface will usually be found to be frayed out ends of the fibres in its structure. This fibrous structure can be well seen as the cartilage degenerates. In places it is hard to tell where the homogeneous cartilage ends and where the fibres begin. They run more or less perpendicularly in the deeper parts and parallel to the surface superficially. Our conclusions agree in many respects with those advanced last year by Dr. Nathan. Not only does the synovia extend over the surface of the cartilage superficially in immobilised joints, but normally in the deeper layers the transition from one to the other is gradual. The branching connective tissue cells of the synovia gradually shade off into the cartilage cells. In addition, the hypertrophied tuberculous synovia hides the peripheral parts of the cartilage, but is not adherent to it. König was wont to trace the entire pathology of the tuberculous synovia from the effusion in the joint, to make the effusion the starting point of the disease, but we believe that it is only a symptom, not a cause. The disease produced in the joint of an animal by the injection of a pure culture of the tubercle bacillus is essentially a tuberculous abscess, and does not imitate Nature's process. The phenomena here are different.

Tuberculosis may be found in one spot in a joint and not in another; hence the unreliability of a pathological examination of a clipping for diagnosis. The whole joint must be examined. In some of our specimens the reports from two laboratories have differed. Tuberculosis does not, except possibly in very rare instances, attack a joint and spread immediately to all its parts. The tissues offer a certain amount of resistance, and as the disease spreads in one place it heals in another. Repair and invasion are going on at the same time. In children, under favorable conditions, the reparative forces prevail and the joint recovers under conservative treatment; in adults, not often.

We have never seen bony union effected by Nature in an adult tuberculous joint. The cure is always produced by fibrous tissue, and we believe that it is never complete. Motion is always possible to a slight degree, at least, and motion lights up the disease sometimes after years of quiescence. We have observed this in several instances. We quote one case—a clinically tuberculous ankle of eight years' duration. A resection of the talus showed that the joint was a mass of fibrous adhesions. The laboratory report read "chronic inflamation, no tuberculosis." A diligent search revealed at length a small cheesy nodule in a joint recess, that under the microscope proved typical tuberculosis. The operation of mobilising an old tuberculous joint therefore by any means is to be undertaken with great caution.

The enlarged villi found in a tuberculous joint often differ in no respect from those found in other inflamed joints. They are a result of joint irritation, and not a clinical entity. There is no such disease as "villous arthritis."

We come now to the practical results of our investigations, and shall state our conclusions in order: 1. We noticed in our specimens of joints a remarkable effort of nature to effect a cure by depriving the joint of motion. 2. In adult joints this effort is never completely successful. 3. Pain is a conservative symptom and tends to healing by decreasing function in the joint. 4. Conservative treatment simply aids Nature by decreasing function. 5. No operation except an amputation above the diseased joint, ever eradicates the tuberculous tissue. 6. An operation to be successful must deprive the joint of function, and must not be followed by secondary infection. 7. If an operation does not deprive the joint of function it will rarely effect a cure. 8. The joints that can be most easily destroyed are the easiest to heal by operation. 9. There are only two tissues in a joint vulnerable to tuberculosis, the synovia and the red marrow. 10. If these two tissues can be eradicated the disease will disappear. 11. A successful operation will cause them to disappear; the synovia will degenerate into fibrous tissue, and the red marrow will lose its characteristic cellular structure and will become ordinary fatty or yellow marrow, practically immune to tuberculosis.

Therefore, the way to cure a joint conservatively is to deprive it of function temporarily. This is rarely successful in an adult, therefore, the way to cure a joint in an adult is to deprive it of function by operation.

As to the operation of curetting tuberculous joints—"bone scraping," etc., we mention but to condemn it. Let us not deceive ourselves, however, with the idea that it has fallen into disuse. A study of hospital statements as well as an inquiry into general methods of procedure, will reveal the fact that it is being practiced every day throughout the country. The custom of opening, scraping, and draining these joints is wide-spread. The use of carbolic acid, iodoform, or iodine with the object of affecting disease in the bone is not rational. Synovectomies have not justified the expectation of those who formerly advocated them, and are nowadays rarely done. Resection is the operation that holds first place. Let us see how the results of this bear out our theory.

Resection of the knee. The knee is the joint that is most easily cured by a resection. If the condition of the patient is good the operation will almost invariably effect a cure. Now, the knee is the one joint in the body in which firm bony ankylosis can usually be secured. A cure is not effected by removing all tuberculous tissue. This is well-nigh impossible. The ends of the bones (cancellous bone with red marrow) are brought together. Bony ankylosis is secured. The joint ceases to exist. The synovia atrophies. The spongy bone is changed to dense bone, the red or cellular marrow gives place to yellow marrow, and the field for the existence of tuberculosis is abolished. The disease disappears because it has no tissue in which to exist. Eventually a central medullary canal is established, surrounded by hard bone. The femur and tibia become one long hollow shaft.[3] In one of our patients, a case of spontaneous bony union following a mixed tuberculous infection of a child's knee, two *x*-ray photographs taken at an interval of about a year, show clearly this canalisation taking place.

We have seen this theory of operation carried out in three knees, operated upon respectively thirteen months, four months and two months ago. The

results confirm our theory. We saw through the patella, but do not divide the lateral or crucial ligaments. The patella may be disected out or left. The tips of the condyles are sawn off, and the tibial cartilages chiseled away. Only about ⅝ of an inch are removed instead of the usual two inches. The wound is sewn up tight, no attempt is made to dissect out the diseased synovia, nor are nails, wires or bone sutures necessary.

Resection of the hip. Whatever method of resection is done, no pretense can be made of eradicating the disease from the pelvis and yet the results are usually good. A dislocation of the hip takes place. The joint as such ceases to exist, and therefore the elements of the joint subject to tuberculosis disappear. We obtain what the French call "Articulation par suspension." Consequently, it seems unwise to adopt any operation that sacrifices the head, neck, and trochanter, when a simpler procedure would suffice. We have proved our theory in two cases.

Resection of the wrist and tarsus. If tuberculous disease in a small bone can be diagnosed in time to remove the bone before the joint is involved the disease may be cured by operation. Otherwise the unfavorable outlook is well known. Why is this? Because no operation has ever been devised that will completely deprive the joint of function and so cause the disappearance of the two elements in it that are subject to tuberculous disease, the synovia and the red bone marrow.

These examples will suffice. We sum up as follows: All treatment of tuberculous joints should be directed to depriving them of function. In children conservative treatment planned on this basis will usually effect a cure. In adults an operation is usually necessary, and the object of this operation should usually be to deprive the joint of function.

LUPUS—ITS TREATMENT BY THE ROENTGEN RAYS.

By CHARLES LESTER LEONARD, A.M., M.D.,
PHILADELPHIA.

The prognosis in lupus vulgaris by other methods of treatment than the Finsen light and Roentgen rays is well summarized by Prof. Jacobi, who says: "The prognosis as regards life is favorable, apart from the occurrence of general tubercular infection, but as regards cure it is absolutely unfavorable in extensive cases. Permanently successful results have hitherto been attained only in recent, limited cases suitable for excision." He further states that it is hoped that better results will be obtained by the Finsen treatment.

The results obtained by the Finsen light treatment have been highly satisfactory so far as their permanence is concerned. It has, however, been found that the maintenance of the costly Finsen lamps and of the staff of nurses necessary to their employment, is a great drain even upon a well-endowed hospital. Not only is the constant attendance of a nurse demanded during each treatment to produce a mechanical anemia of the area treated, but also an area of only half an inch in diameter can be treated at one time. Thus the whole area must be gone over, time after time, in these small areas. The time consumed in treating an extensive case of lupus is, therefore, very great. Since the smaller ultra-violet lamps have been proved to be practically worthless in treatment, the effective treatment by the Finsen method is confined entirely to hospitals having the original Finsen lamps and an endowment capable of maintaining them.

In conjunction with many other dermic lesions lupus was subjected to experimental treatment by the Roentgen rays. To-day its successful treatment by this method is acknowledged as a demonstrated fact, as is likewise the treatment of epitheloma and rodent ulcer, while in the severer forms and rebellious cases of eczema and acne the Roentgen rays are found to succeed where all other methods of treatment have failed.

It might be said of all these dermic lesions, as well as of tuberculosis cervical adinitis, that they are more amenable to Roentgen treatment in their earliest stages, that they would all, at that time, yield to fewer treatments, and that in every case the results, especially the cosmetic results, are better the earlier the patient is sent for treatment.

The Roentgen treatment has the particular advantage over the Finsen treatment of lupus, in that it is more rapid in its effects and consumes less time in its application, since it can be applied over the whole area and its rays have greater therapeautic power. In consequence, the treatment is more expeditious, and less expensive, but it should not be supposed that it is inexpensive. The maintenance of the Roentgen equipment, and the renewal of apparatus, resulting from the rapid advances which this department of scientific medicine has made, have shown both to hospitals and private individuals that the necessary chemical energy employed in this treatment can only be produced at the cost of mechanical wear and tear upon appartus which is intricate and expensive.

The Roentgen treatment has been employed successfully not only in lupus vulgaris, but also in lupus erythematosus. It is also effective in the early stages before ulceration has taken place, the deep-seated areas disappearing without the production of ulceration or scarring. This is in marked contrast to the Finsen treatment where sloughing and ulceration are necessary before the deeper portions of the lesion can be affected by the ultra-violet rays. The Roentgen rays, therefore, have the advantage of reaching the superficial and deep portions of the disease at the same time and over the entire area without the necessity of breaking down the skin over the diseased area where it is intact, and thus producing an ulcer and scar tissue in securing a healing.

It must be self-evident that the achievement of valuable results with this therapeutic agent depends largely upon the experience of the individual employing it, and his ability to adapt to the patient the quality and quantity of radiation which the lesion demands in each stage of recovery.

The three cases cited below are illustrations of the results which are produced in severe cases, and show that since the advent of this method of treatment the prognosis as regards cure is favorable even where the lesion is extensive and rebellious to all other forms of treatment.

The cases, seen early, when there is only a small area involved, with only four or five lupus nodules, are readily cured and leave little or no evidence of their having existed, if the surface of the skin is not already broken. Two of the cases are of extensive

lesions of lupus vulgaris of the face, both involving the nose, while the third is a rebellious case of lupus erythematosus. It is particularly noteworthy that in these cases where there is great deformity and loss of tissue by ulceration, nature will, when aided by the alterative and stimulant action of the Roentgen rays, produce a restoration so near to the normal as to seem almost impossible.

This was particularly noticeable in the case of Miss Catherine B., Aet 33, who presented a typical lesion of bat-wing lupus. The nose was eroded down the cartilage, while the disease extended in two wings beneath each eye to its outer side. In addition, she had an area of ulceration two by four inches, involving the scalp upon the top of her head, which presented typical lupus nodules in its base. In the process of healing upon the nose, new skin did not form until healthy granulations had raised their level to that of the surrounding normal skin so that the original form was restored.

The new skin covering the entire diseased area was soft, pliable, and more nearly like normal skin than scar tissue. Upon the scalp the disease had reached and denuded the bone, so that an area was left bare.

In the second case, that of Mrs. E. Y., Aet 38, the disease involved the end of the nose, but was seen before much loss of tissue had taken place. The entire end of the nose, including the alae, was intensely swollen and dark red in color, the inflammation extending in a less degree to the cheeks and lip. On the nose there were three ulcers, each one-half inch in diameter, but superficial. After the nose had healed and had assumed a nearly normal shape, the patient first called attention to a fissured ulcer in her tongue, that extended on its dorsal surface from tip to base. There was no glandular involvement, although the ulcer had been present for over a year, while a dark area showing lupus nodules in the soft palate made its etiology evident.

Under Roentgen treatment the ulcer in the tongue healed except that portion low down forming the anterior wall of the throat, which the rays did not reach. The ulcer in the soft palate perforated and its margin healed. An intercurrent attack of erysipelas prevented the patient, who lived out of town, from reporting for some weeks, but had the beneficial effect of healing the ulcer at the base of the tongue. She has been seen five years after the cessation of treatment and has remained perfectly well.

The following case of lupus erythematosus, although not so severe a lesion, is reported because of the rebelliousness to radical treatment of other kinds. Miss J. T., Aet 28, was referred for treatment five months after the diseased area had been curetted. She presented upon the temporal region a patchy area one by two inches, with bright red margin covered with adherent scales. The centre of this area was covered by atrophic cicatrical tissue, through which visible darkened areas were seen. Under the Roentgen treatment there were repeated desquamations over the entire area, and a final healing with no discoloration of the skin.

The progress which has been made in the treatment of lupus by the Roentgen rays is made evident by such results in these grave cases, and shows that the prognosis for recovery is not "absolutely unfavorable in extensive cases as regards cure," and that "permanently successful results" are attained in all cases, and are not to be expected "only in recent limited cases suitable for excision."

OBESITY: ITS RELATION TO OTHER DISEASES AND ITS SIGNIFICANCE; ALSO SOME OBSERVATIONS ON PROPHYLAXIS.

By I. B. KRONENBERG, M.D.,

PITTSBURG, PA.

We frequently meet with a certain class of patients, usually past middle age and above the average in weight, who suffer from a syndrome of symptoms so diversified and indefinite that we are puzzled as to how to classify them properly on our case-record cards. These symptoms are referred to different parts of the body and to various organs, and are often severe enough to suggest serious organic disease. But when we find on careful examination that the important organs are apparently in normal condition, and no one symptom, or set of symptoms, sufficiently prominent to indicate at least where the enemy might be lurking, we are pretty apt reluctantly to index the case as neurasthenia, neuralgia, rheumatism, etc., being conscious at the same time that we are merely indexing a symptom, or group of symptoms, and not the disease itself.

These patients usually complain of shortness of breath, dizziness, headache, backache, lack of energy, constipation, loss of appetite, "indigestion," puffiness of face, swelling of the legs and feet, insomnia, irritable temper, indefinite aches and pains in different parts of the body, commonly referred to as "rheumatic" or "neuralgic," and a great number of other symptoms that, although they apparently bear no relation to each other, we feel sure are all due to one common cause. And yet these cases receive so little attention in the text-books and medical literature generally that we don't even know how to classify properly a case presenting this particular combination of symptoms.

If the patient happens to be very stout we diagnose the case as obesity. But very often the patient's weight is not sufficiently above normal to account for any symptoms at all, and even in those cases that properly come under the head of obesity it would be unreasonable to assume that the mere presence of an excessive amount of adipose tissue is, in itself, responsible for all the symptoms that may be present. It is obvious, then, that there must be some underlying pathological condition that is responsible for all the mischief; and when obesity is present it must be regarded as merely a symptom of this general condition rather than a disease in itself.

Faulty metabolism is the etiological factor in all these cases; and just as any other disease of a known origin finds expression in different forms—the symptoms in any given case being modified by the age, habits, temperament, etc., of the patient—so the symptoms of faulty metabolism differ according to the same conditions.

Metabolism is the highly complicated chemical process going on in the body in the assimilation and utilization of ingested food. The ultimate uses of food are two-fold: First, to supply the body with materials for growth or renewal of tissue; second, for the production of energy, in the form of heat and motion. During infancy, childhood, and adolescence a considerable part of the food taken is used up in the development of the body. When the body has attained its full growth the requirement of food for this purpose is greatly reduced, and any excess of food taken, as a matter of habit, is

at this period generally disposed of by work or exercise. But after middle age the functional activity of the body is much diminished, requiring much less food for the production of energy. And if, as is often the case, the habit for satisfying a vigorous appetite is continued, it is obvious that much more food is taken than is required for maintaining the bodily functions, and a great deal of it will be stored up in the body as unused energy, in the form of fat.

Now, there are certain noxious by-products formed as a result of tissue combustion, which are eliminated by those organs whose function it is to dispose of this waste-product. And as muscular exercise is a very essential aid in the proper elimination of these poisonous materials, it can be readily seen that if the proper amount of exercise is not taken, and the circulation of the blood is allowed to become sluggish, these substances will, of course, accumulate within the body. It follows, then, that the same conditions, or habits, that encourage the development of obesity also favor the accumulation within the body of certain poisonous irritant materials which, in the course of time, will pave the way for one of several evils.

The kidneys are put under a tremendous strain, and are likely to break down. The arteries become affected through the presence of toxic substances in the blood circulating within them; they undergo some changes in structure, both as a result of this irritation, and also because the arterioles are in a state of spasmodic contraction (probably a provision of nature to raise the blood-pressure and propel the blood more rapidly to the organs of elimination—the kidneys, lungs, etc.) which weakens their muscular coats. Arteriosclerosis develops, together with its concomitant train of trouble.

The heart also is affected in two ways. First, being itself a part of the circulatory system it, too, is apt to share in the changes taking place in the arteries. Second, as the blood-pressure is generally raised under these conditions, the heart is forced to pump the blood through greater resistance, and if it is unequal to the task heart failure is likely to result. The nervous system, too, is affected by the irritation of these products of faulty metabolism. Ill-temper, nervousness, insomnia, etc., are some of the earliest indications of trouble, and many cases of neuralgia are due to this cause. These patients suffer from aches and pains in different parts of the body; and many cases of so-called muscular rheumatism, rheumatic gout, etc., are really cases of autointoxication, and these different pains that migrate from place to place, affecting first a joint and then a muscle, then another muscle, or a group of muscles supplied by a certain nerve, are produced by the presence of these toxic materials in the system and their irritating effect upon the various nerves.

As already observed, these conditions are primarily caused by improper elimination of waste products from the system, and sedentary habits and over-indulgence in food and drink favor the accumulation of these substances within the body; it is plain, then, that obesity is merely one of the indications of faulty metabolism, and a patient who accumulates much more fat than is normal for his height, race, and family peculiarities will, sooner or later, show other evidence of the disease.

About a year ago the writer started a series of experiments in the treatment of obesity with electricity and other physical methods, the details of which, together with case records, results, etc., will be described in a future article. The subjects for these experiments were comparatively young people (mostly women) who, aside from being stout were apparently in perfect health. And yet, when putting these subjects through an examination before starting treatment, we so often found evidence of Bright's disease, diabetes, high arterial tension, etc. (a number of them presented the condition commonly spoken of as "plethoric") that the relation of these conditions immediately became apparent. And, indeed, upon closer inquiry we frequently found that the patient had noticed a little shortness of breath, swelling of the limbs, weakness, nervousness, etc., for some time, but did not consult a physician as she attributed all symptoms to her burden of adipose tissue, for which she knew "there was no cure except starvation."

In making examinations for life insurance companies we are also occasionally surprised to find evidence of diabetes, disease of the heart and kidneys, etc., in persons who are apparently in good health, but not nearly so often as in examining patients affected with obesity. In connection with this point the writer is at present gathering statistics from the records of life insurance companies for future publication, but the following quotation from a paper by Dr. J. W. Fisher, Medical Director of the Northwestern Mutual Life Insurance Company, will serve our present purpose. He says, "The weight of an applicant for insurance is an important factor. A record of 120,000 insured lives, covering a period of thirty years, demonstrates that the death loss is excessive on persons whose weight is 20 or more per cent. above the average. The statistics derived from the records referred to demonstrate that the greater the weight, the greater the death loss. * * * Persons of excessive weight, as a rule, are sub-standard risks * * * except in exceptional cases where the excessive weight is a family trait and longevity is shown in the family record, and weight but slightly over 20 per cent. in excess of the average. Over-weights are prone to disease of the arterial system, diseases of the heart, apoplexy, and premature arteriosclerosis. They are peculiarly liable to contract diabetes and rheumatism. They usually take insufficient exercise, are generally high livers, and are frequently free users of stimulants, particularly malt liquors. They succumb easily to accidents, surgical operations and, as a rule, to acute diseases."

The relation of these conditions to obesity was further emphasized by the therapeutic test, for they were always improved, and in some cases, cured, (particularly the diabetic cases) as progress was made in the reduction of excessive weight.

Now, we know that many people owe their lives to examinations for life insurance, when some conditions were discovered in the incipient, and often curable, stages that would have terminated fatally if left untreated. We also know that many dangerous and incurable diseases can be prevented if the conditions leading up to them are recognized in time, and the proper means taken to check them. Isn't it our duty, then, to devise some means by which we should be able to discover these troubles early and warn our patients in time, instead of leaving them to the mercy of a possible life insurance examination?

Prevention is the highest aim of modern medicine, and all our efforts are mainly directed to the

prevention of disease. But under the present conditions we can only control diseases of extrinsic origin, *i. e.* diseases originating from causes outside of the body (*e. g.* infection) because in those cases the physician is called early, and by the use of quarantine, vaccination, etc., he prevents the disease from spreading to other persons; and the progress of the disease in the person already affected is modified, and complications avoided by the proper management of the case. Whereas in diseases of intrinsic origin, that is, those originating within the body (*e. g.* chronic Bright's disease) the onset is extremely insidious and gradual, with no symptoms of sufficient importance, as the patient thinks, to require medical attention until the disease has reached a dangerous stage. The question, then, naturally arises how is the physician to know of the existing trouble in time to warn his patient of the impending danger.

The only hope of solving the problem, it seems to me, is in the general adoption of a prophylactic system similar to the one now used for prevention of puerperal eclampsia, for the two classes of cases are very similar. Having learned from sad experiences that a pregnant woman is peculiarly liable to kidney break-down, and knowing that there are no marked symptoms to indicate any kidney trouble until the explosion occurs, when, only too often, it is too late for help, we do not wait until we have reason to suspect albuminuria before making a test, but explain to the patient the necessity of such precaution and have her submit a specimen of urine for examination at proper intervals. So, in the class of cases under discussion, we know that such a catastrophe as apoplexy, uremic convulsions, or heart failure, that so often carries off people who are comparatively young, is merely the culmination of a series of pathological changes that have been going on for some time; that in a majority of cases a careful medical examination would have disclosed these changes quite early; and that by correcting the errors in the person's mode of living, regulating his diet, exercise, sleep, etc., and proper medication and physical treatment when indicated, we can cure a great many of them and certainly prolong the lives of a majority of them. Knowing, also, that these changes are apt to begin any time after the age of 40 or 50 (much earlier in men who are high livers, and spend much time in their office under great business strain) and that faulty metabolism is the chief factor in starting almost all these troubles, and that obese persons are more prone to develop these conditions than persons of average weight. Would it not be a wise and beneficent plan, then, to educate our patients who have passed middle life, and especially those affected with obesity, to the importance of periodic examinations, the same as we have educated our obstetric patients? Of course, there will be many who will disregard our advice, being unable to see the necessity for such examinations. But the same indifference is often encountered in obstetric practice, and yet, in spite of occasional neglect and carelessness, we feel confident that many useful lives are saved each year through this precaution.

The writer happens to be acquainted with the recent case of a young woman, about 28 years old, intelligent and a member of a wealthy family. This young woman was the personification of health and vigor, had passed through one normal pregnancy and confinement, but during the fourth or fifth month of her second pregnancy she was suddenly seized with uremic convulsions and died in a few hours. Her attending physician, a man of the highest professional standing and among the leading medical men in this city, sadly declared that he had repeatedly asked her to send a specimen of urine for examination, but she thoughtlessly neglected it.

In speaking or reading of a case like this, do we get discouraged and say "there is no use trying?" Certainly not! We rather hold up the case as an example, in speaking to other patients, to show the terrible price they are liable to pay for neglecting the "ounce of prevention." So, too, we read in the newspapers almost daily of men prominent in business, politics, and science, often in the prime of life, dying suddenly of heart failure, apoplexy, or "acute indigestion" (?), and it is generally reported that these men were never sick, and that neither they or any member of their families had the least intimation of anything being wrong with the heart or arteries!

In the course of conversation, a few days ago, with a man prominent in the financial circles of this city, this man remarked to the writer, "Why is it that I get my teeth examined regularly but never get *myself* examined?" The answer, to my mind, is quite plain. The value of such physical examinations has never been pointed out to him, and relying on the old saying that "a man is as old as he feels," he never thought of going near a doctor so long as he felt well. But, as we know that after middle life this is not a true guide to the actual physical condition, and that, in fact, "a man is as old as his arteries," we should cultivate this new and promising field of preventive medicine, and explain to those members of our families who have passed the half-century mark, particularly if they are burdened with superfluous flesh, the necessity of a physical examination at least twice a year, and we shall certainly be rewarded for our labors by good results accomplished.

Suite 400, Pittsburg Life Building.

AN HISTORICAL NOTE ON THE SO-CALLED LUDWIG'S ANGLE OR THE ANGLE OF LOUIS.*

By EDWARD H. GOODMAN, M.D.,

PHILADELPHIA.

Our slavish following of German thought is well illustrated by the nomenclature given to that prominence of the thorax corresponding to the junction of the manubrium with the body of the sternum. It will be a matter of more than passing interest to many physicians to learn that Ludwig's angle is so called not after any German "Ludwig," but in honor of the great French clinician, Louis. "Ludwig" is the German translation of the French name, and so the real identity of the original discoverer of the prominence has been masked.

Ludwig's angle is so called in honor of the great clinician (born April 14, 1787, died August 14, 1872), who is supposed to have described it for the first time. I say "supposed" advisedly, for heretofore writers on the subject have been unable to locate the place in Louis' writings where the pathological prominence of the sternal angle was first described. Ebstein (*Münchener medizinische Wochenschrift* 1909, 46, p. 2377) is the latest writer on this anatomical landmark, and he states he was unable to find any discussion of this angle in the writings of Louis.

*Read before the College of Physicians, March 2, 1910.

Earlier writers have reached the same conclusion, as the following from Ebstein will show:

Braune, in 1888, having in preparation a paper on the anatomical and clinical importance of the so-called "Ludwig's angle," searched carefully the works of Louis for the original description. "To my great disappointment and astonishment," he writes, "I could find nothing pertaining to the sternal angle and its relation to phthisis." Accordingly he applied to his teacher, Thierfelder, at that time director of the medical clinic in Rostock. The latter was unable to give any information, as the following will show: "The statement that you have been able to find nothing in Louis' writings concerning the sternal angle seems extraordinary. I learned from Bock and Oppolzer (his former professors) that the sternal angle consisted in a sinking in of the manubrium in phthisis, as well as a protuberance in emphysema, but that the former was the real "Ludwig's angle." I was naturally under the impression that Louis had first called attention to its semeiotic importance in phthisis. I could not help, therefore, searching Louis' writings and the text-books on special pathology and physical diagnosis, but I found nothing which throws light on the name in question." Braune remarked after hearing this, that he believed the place would be found where the reference is made to this sign, for he felt the name was not "rein aus der Luft gegriffen."

Hyrtl (1882), one of the acknowledged bibliophiles of his time, simply states, "Louis first called attention to the pathological significance of this angle, and he has been honored by Conradi in having it called "Angulus Ludovici." Conradi (1848), in turn, describes the angle as "the more or less marked protuberance of the junction of the manubrium with the body of the sternum, to the development of which by retraction of the upper thorax, the attention of pathologists was first called by Louis."

Ebstein states that there is really nothing in the writings of Louis, which deals with the clinical importance of the sternal angle in any disease. He seems on this account to advocate the dropping of the name angulus Ludovici, and the substitution for it of the term "sternal angle."

Feeling that Louis must have called attention to some relation between the upper part of the sternum and a morbid condition, and that this description must be somewhere in his writings, I began a search of Louis' works. No description of the condition was found in any of Louis' writings, but in a work on emphysema I found the description of a bulging of the upper part of the chest, usually unilateral, and usually extending to the third or fourth rib.

The French article is to be found in the Mémoires de la Société Médicale d'Observation, 1837, Tome premier, p. 194, and is entitled, "Recherches sur l'Emphysème des Poumons." It was translated into English in 1838 by T. Stewardson, Jr., a Fellow of the College of Physicians of Philadelphia, whose translation I found in the Library of the College of Physicians in a book called "Medical and Surgical Monographs," p. 512.

"Configuration of the Chest.—I. In the patients who quitted the hospital more or less relieved, the form of the chest was carefully examined in 37 cases, and in every one it had undergone some change from the natural condition. This change was uniform throughout the whole chest in a young woman 23 years old, whose dyspnea dated from early infancy, and had become paroxysmal about three months before her admission into the hospital. Her chest was everywhere more prominent than in the normal condition, approaching to a globular form, and equally so in corresponding points. This prominence was formed by the ribs and the intercostal spaces, which latter were not depressed as they are in the natural condition, especially in thin persons. In the other cases, the change of form was similar in character but partial in extent, the prominence being limited to one side of the chest except in three persons, where two prominences were observed, whose surfaces were irregular, the one being on the right side and the other on the left, and not precisely in corresponding points.

"The prominence alluded to commonly commenced under one or other clavicle, and extended downward to near the mamma, or even a little beyond in some cases, its breadth being three or four inches. It is impossible, with a little attention to have mistaken this prominence, when it was well marked, for an original defective organism, since both the ribs and the intercostal spaces contributed to form it. It was likewise impossible to have attributed it to a pleuritic effusion, because the dilatation of the chest which sometimes accompanies the latter, is general, and also more above than below. It could not, moreover, have been confounded with that which results from a collection of liquids, except when it existed over the precordial region, and was limited to it, which occurred in three cases, and in which it might have been asked whether it was not owing to an effusion into the pericardium. But the absence of the other signs of pericarditis did not allow us to remain very long in error upon this point. The prominence which is consequent upon an aneurysm of the aorta is generally more circumscribed and better marked; so that the observation merely of the prominence which we have described, of its form and extent, has pointed out to us almost certainly the existence of an affection of the chest, which was neither phthisis, nor dilatation of the bronchia, nor pleurisy, nor aneurysm of the aorta, nor even a pericarditis (except the few cases in which there might, at first, be some doubt upon the subject). The dyspnea, too, having been present for a certain length of time in these cases, and with the characters noted in the preceding paragraph, we are obliged to consider them as so many examples of emphysema of the lungs.

"Three times only out of six cases, where the back was examined, was a prominence similar to that which has been described found posteriorly. The preference which this elevation appears to have for the anterior of the chest, is in accordance with that we have already stated as regards the lungs, viz., that their free border and the neighboring parts were the principal seat of emphysema, and the point where the latter was most developed.

"Further, the prominence we have been speaking of was not equally frequent on both sides; it occurred eleven times only on the right, and twenty-three times on the left. Notwithstanding that the numbers are small, it is not easy to suppose that the above difference is altogether accidental, since we arrived at a similar result, or thereabouts, by consulting separately the cases recorded by Jackson and myself. In fact, the proportion of the elevations on the left side to those on the right, is 15.7 for the one, and 8.5 for the other.

"This result, however, is, to a certain extent, in opposition to one which was announced in the chapter on pathological anatomy, viz., that both the

amount and frequency of emphysema appeared to be the same in each lung. But may it not be that the unequal frequency of the elevations on the left and right side, among the patients of the first series, was temporary, and that it disappeared in proportion as the disease became more advanced? By this supposition the above contradiction would only be apparent and opposite results would be harmonized. But it is merely a supposition and experience must determine the question.

"In emphysema there is also found another prominence, different from the one above described, and which I have already observed, occurring in a different part of the chest, behind the clavicles. This elevation existed in every case where it was looked for, with one exception, which presented itself in a thin man, aged 43 years, and in whom the supraclavicular regions were both hollow, although there can be no doubt of the existence of emphysema in his case, there being a slight prominence anteriorly on one side.

"This last mentioned elevation, the presence of which might have been readily inferred from that on the other, was mostly confined to one side, or that upon which the first existed. The only exceptions to this were found in four cases, where the emphysema was remarkably developed, and where both supraclavicular regions were manifestly less depressed or more prominent than in the natural state, though in different degrees. The elevation now alluded to was especially observable in old men, in whom the side of the neck corresponding to it, in cases where the change of form was considerable, appeared, if we except the flaccidity of the integuments, like that of a young man, presenting a convexity superiorly, while on the opposite side there was a more or less decided depression. This double elevation, which is found only in emphysema, has enabled me to recognize this affection in more than one case, where subsequent examinations have confirmed the first diagnosis.

"II. In those who died, the form of the chest was attended to and in every one it was found to have suffered some change anteriorly. In seven the prominence was simple—*i.e.* limited to one side. It was present both at right and left in the eighth part of the cases, and at different points.

"Three times out of seven it was remarked on the left side—a result the inverse of what was found in those who left the hospital more or less relieved, and which is to be accounted for, no doubt, by the smallness of the numbers; for in the patients of the present series, when regarded anatomically, and in greater number, both lungs appeared to be equally affected, or thereabouts. Further, in the class of cases now under examination, the greatest development of the emphysema corresponded to the prominence, or prominences, indicated; so that it is impossible to have any doubt as regards their importance, or the cause producing them, in the disease before us.

"As for the supraclavicular regions they were more prominent on one side than the other in the three cases where they were described, and, as in the patients of the preceding series, this elevation was found on the same side as that which had its seat on the anterior portion of the chest, or on the side where the emphysema was most marked."

Further on we learn the method Louis adopted for the proper recognition of this deformity.

"As regards the two forms of prominence which we have been considering I will observe that the greater their importance in reference to the diagnosis of emphysema the greater should be the care in determining their existence in individual cases, in order to avoid the mistakes into which we might fall in this respect. For this purpose, if we wish to determine the form of the chest anteriorly, the patient in bed, he should lie upon his back and be inclined to neither side; without which latter precaution the anterior part of the chest might appear prominent when it was really not so. If on the contrary we wish to determine the form of the supraclavicular region, the patient should sit upright without bending to either side, the arms hanging along the side or crossed in the same position, and if the difference between the two regions is not evident the patient must stand up out of bed, taking care not to support himself on one hip and with his arms placed as before mentioned. In fact, it would be proper in every case to place the patient in this position, in order to determine more accurately the various alterations of form which the chest may present." (P. 521.)

My search, so far as finding any direct reference to the articulation between the manubrium and the body of the sternum, was a failure, but I believe an important fact has been brought to light. It is most probable that Louis never mentioned this articulation in his writings, certainly not in the work on phthisis, where, according to Anthony (quoted by Ebstein), the original description appears. It is improbable that any work of Louis containing such a fundamental discovery as this could have been lost sight of. Cannot it be that the pathological prominence of the upper part of one side of the chest above described, is the original angle, and that anatomists have wrongly called the projection formed by the union of the first and second portions of the sternum, Ludwig's Angle? There must necessarily result from a unilateral bulging of the upper four ribs, some prominence of the sternum, presumably at the articulation with the manubrium. In course of time the unilateral prominence has received less notice, and attention has been drawn instead to the projecting sternum. Pathologists first, and then anatomists have named the manubrium-gladiolus articulation, Ludwig's angle, wrongly as it appears to me. If any prominence should be called Ludwig's Angle or Angle of Louis, it should be the abnormal prominence seen as the result of disease, and not the normal joint.

These quoted descriptions are, I believe, sufficient to justify the honor bestowed on Louis' name in calling the peculiar prominence of the sternum and ribs seen in disease, the Angle of Louis. This article on emphysema has apparently been overlooked by earlier German authorities and now recently by Ebstein. A perusal of Louis' great "Recherches anatomico-pathologiques sur la Phthisie," published in 1825, revealed no mention of any particular deformity of the chest, and this was likewise the reward of Ebstein and his predecessors. It is only fair to suppose, therefore, that Louis had not observed it in phthisis (in fact throughout the article on emphysema this is so stated), and that it first attracted his attention in emphysema.

Louis appears to have been the first to describe this peculiar contour of the upper sternum, and therefore is entitled to the honor of having this prominence named "Angulus Ludovici." But it is preferable to discard the term "Ludwig's Angle," and I would suggest the adoption of the term "sternal angle," or "Angle of Louis."

New York, July 23, 1910.

CHRONIC PROGRESSIVE PRIMARY POLYARTHRITIS IN CHILDHOOD.

A DOUBLE tendency in clinical medicine is in evidence at the present day, manifested respectively in the separation of new syndromes and the identification of widely differing complexes under a common pathogenic conception. New syndromes, usually connected with the name of the describer, are mentioned with ever-increasing frequency. From the opposed standpoint we have whole series of clinically dissimilar processes united under such designations as parasyphilis and paratuberculosis. Many acute processes having at first sight little in common are now familiarly spoken of as forms of sepsis. Where once we recognized as sepsis only certain forms of surgical or puerperal infection, the term is now used indifferently for typhoid fever, generalized pneumococcic infection, or any actual or conceivable condition in which bacteria enter the blood in a virulent condition and proliferate therein. All bacteriemias, whether intense or mild in degree, may present certain traits in common.

New syndromes are fully represented in the domain of the locomotor apparatus, and in lesions of the serous and synovial membranes. The late Prof. Hoffa described some three years ago a multiple affection of the joints in children, characterized by premature atrophy of the bones and muscles. This disease began as a rule in the phalangeal articulations. No doubt the Röntgen rays were of material assistance in isolating the syndrome. The joints appeared to be enlarged, but the intimate alterations consisted of atrophy of both cartilage and bone, the articular surfaces being simply compressed together with resulting fusiform enlargement. The original seat of the mischief appeared to be the joint capsule, which in turn led to atrophy of the articulating surfaces. To the joint alterations succeeded muscular atrophy, first of the extensors and then of the flexors. The condition was eminently progressive, extending from the smaller to the larger joints, as from the hand to the elbow.

In the *Münchener medizinische Wochenschrift* for June 14, F. Brandenberg describes cases of this syndrome, and his attempts to treat them with thiosinamine, thyreoidin, etc. He also discusses the intimate nature of the malady. In its inception it may be complicated with inflammations of the great serosæ and endocardium. In other words it presents some points of analogy with Bamberger's disease, or polyserositis, which, occurring under numerous clinical forms, tends to affect the serosæ essentially and the joints only incidentally. In the syndrome at present under discussion, these conditions are apparently reversed, for the joints are involved primarily, the large serosæ only incidentally. Brandenberg regards chronic progressive polyarthritis of childhood as a condition *sui generis*, which is in no wise related to acute polyarticular rheumatism. It shows no tendency to respond to salicylic acid and other antirheumatic remedies. Naturally it possesses only limited analogy with arthritis deformans in advanced life. The treatment must be wholly symptomatic, designed to prevent muscular atrophy and ankylosis. It will be remembered that polyserositis with occasional incidental implication of the joints is a multiform affection. Occurring as an acute process it may be said to represent a generalized acute articular rheumatism, in which the large serosæ are attacked with the joints. Such cases are extremely rare, although it is not uncommon for a single serosa like the pericardium to participate. Chronic polyserositis, which presents a number of individual syndromes, is regarded by some as a paratuberculous process. In all cases of such type we are forced to assume the existence of some infectious principle or product in the circulation.

THE PREVENTION OF TYPHOID FEVER.

AT the annual convention of the Carolina Municipal Association, held in Winston-Salem, N. C., June 2 and 3, 1910, Dr. L. L. Lumsden of the Public Health and Marine-Hospital Service discussed what the mayor and city council can do in the prevention of typhoid fever. The disease is especially prevalent in the South, a fact which, according to Lumsden, may be attributed to the following conditions: 1. Faulty sewage disposal, incident to the relatively large rural population, and particularly, as pointed out by the investigations of Stiles, to the large percentage of negroes in the population. 2. Climate, the long periods of warm weather when there are additional agents for the transmission of the infection, such as flies and other insects and when greater quantities of uncooked foods and beverages are consumed, and there is probably increased individual susceptibility to the infection.

Lumsden tabulates the preventive measures which the mayor and city council may take as follows: (1) Become informed as to the nature of the infection, its modes of spread, and the methods to prevent it. (2) Make disease prevention a conspicuous policy of the administration. (3) Make efficiency the primary basis of appointments to positions in the health office. (4) Provide adequate salaries for health officers. (5) Appropriate funds for sanitary improvement as liberally as the taxation rate will allow. (6) Provide for the collection of mortality and morbidity statistics so that the results of sanitary work may be known. (7) Provide for the proper care of the sick. (8) Keep in close touch with and support the health officer in his work.

(9) Cooperate with the authorities of other municipalities of the State and of the nation. (10) Teach by precept and by example the precautionary measures.

No argument is required to drive home the fact that the prevention of typhoid fever in cities rests mainly with the municipality. If a mayor and city council are indisposed to insist that the sanitary arrangements are properly supervised, then diseases, and typhoid fever in particular, are certain to occur and to spread. There was a time when politics held so large a sway in the government of American cities that sanitation was neglected and the health of the community was at the mercy of men ignorant of and indifferent to the laws of hygiene. A remarkable change in this respect is now taking place. The question of public health is beginning to loom large in municipal, State, and national politics, and those in office are afraid to offend too obviously the growing health sentiment of the people. So far as typhoid fever is concerned much headway has been made in preventive measures in the Northern States. The population generally has decided to have an unpolluted water supply and a fairly pure milk supply, and although neither of these supplies is wholly satisfactory, yet great progress has been made and is being made in this direction. Lumsden shows how municipalities can assist further in safeguarding the public health by paying particular attention not only to the water and milk supplies, but to sanitation in general. It must be borne in mind that there are other means of conveying typhoid fever than milk and water, and that the fly, the typhoid fly, is more dangerous than the most heavily sewage-laden stream.

The Tubercle Bacillus in "Cured Cases."

The identification of a single tubercle bacillus in the sputum of a patient suffering from a cough is by most people considered quite sufficient for a definite diagnosis of tuberculosis and for the institution of systematic treatment even in the complete absence of all physical signs in the lungs. Such an attitude is unquestionably correct, and the immediate beginning of treatment in such cases has probably saved many from chronic invalidism or an early death. Such patients as a rule, however, do not feel especially ill, are fairly strong, are ambitious, and especially if they have been told that a few weeks in the mountains will cure them, are apt to be restive under the prolonged rest and absence from their daily work. The important question then arises as to when such patients are to be declared to be cured, and whether or not they may be permitted to return to their former life in the city. As they at no time have shown physical signs more than could be explained by a mild bronchitis, examination of the chest is of little value in deciding the question; absence of fever and gains in weight are so commonly present in those with active processes during the life in the sanatoria that they are of but little value as evidence. In the majority of cases the final decision rests upon the presence or absence of the tubercle bacilli in the sputum, and a not uncommon routine procedure has been that other signs being absent the failure to find the organisms in the sputum on three successive examinations is sufficient evidence upon which to declare the patient "a cure." During the last few years, however, great advances have been made in the technique of sputum examination. By the introduction of the antiform and other homogenizing and digesting methods the search for the tubercle bacillus has become a much less haphazard method and a much more thorough procedure. These various methods vary in detail, but all seek for one result, the destruction of mucus, cells, and in fact all of the contents of the sputum except the tubercle bacilli themselves, and then their concentration by centrifugation so that all of the organisms in a specimen of sputum may be collected upon one or two microscopic slides. In the *Berliner klinische Wochenschrift* for June 6, 1910, J. A. Finkelstein has made a careful comparative study of the ordinary smear and that prepared by the antiform method and has found that by the newer method the organisms appear from eight to ten times as numerously as by the older and simple process of smearing. Of especial interest, however, is the report of fifty-two patients who, though they at one time had had tubercle bacilli in the sputum, had been declared cured on the grounds of the absence of symptoms and signs and negative sputum examinations. Whereas the usual smear confirmed the cure in every case, the antiform method of preparing the specimen demonstrated the organisms still to be present in twenty-one of these fifty-two cases, in numbers varying from seven in the entire preparation to an average of six to a microscopic field. In the face of such findings it is apparent that more care is required in declaring patients cured of tuberculosis, that many cases which are overlooked by the ordinary methods of sputum examination are in reality harboring bacilli in large numbers, and that repeated examinations of the twenty-four hours sputum by some of the newer methods should be negative before a patient is declared cured of the disease. On the other hand one must be certain that the organisms found in the sputum are really tubercle bacilli and not mere simulacra.

Preventable Causes of Insanity.

In the June issue of the *Popular Science Monthly* Dr. Thomas W. Salmon of the Public Health and Marine-Hospital Service writes on two preventable causes of insanity. It is almost needless to say that these causes are syphilis and alcohol. During the past year 664 patients, or 12 per cent. of all the 5,301 new cases admitted to the New York State hospitals had general paralysis, and 638 cases of the alcoholic psychoses were admitted to the same institutions in the same period. This is to say that more than one-fourth of all first admissions were due to these two causes. Considering the 1,302 cases of general paralysis and of alcoholic psychoses in detail Salmon brings out certain significant facts relating to sex and environment. With regard to the male admissions, environment does not appear to have had a very marked influence upon the prevalence of the alcoholic psychoses, but the percentage of cases of general paralysis in men was nearly three times greater in the admissions from cities than in those from the country. For women the percentage of cases of general paralysis from cities was twice that from rural communities, but the percentage of admissions with alcoholic psychoses was seven times greater for cities than for the country. As Salmon remarks, this is elo-

quent testimony to the influence exerted by the back room and the "ladies'" entrance of the city saloon, but the most striking feature of these figures is that 42 per cent. of all the male admissions from cities were for general paralysis and the alcoholic psychoses. Possibly Salmon somewhat overrated the influence of alcoholism of parents upon their offspring. At least his figures are in direct opposition to those recently got together by investigators connected with the "Francis Galton Laboratory" in England, which seemed to support the proposition that parental intemperance had no causal relation to filial degeneration. Another British authority, Archibald Reid, propounded similar views in his work on alcoholism published in 1901. Indeed, in spite of the opinions of German authorities the question of the influence of alcoholism in parents upon their progeny has not been by any means finally settled. Nevertheless, there is no doubt that syphilis and alcohol are directly responsible for more cases of mental derangement than any other two causes. Salmon, too, is absolutely correct when he says that the lesson of the statistics referred to is full of hope and encouragement as showing that a large proportion of all cases of insanity is found to be due to causes within our own control, since it is justifiable to speak of syphilis and alcohol as two preventable conditions.

Socialism and Medicine.

As a rule the socialist is antagonistic to the medical profession. One cannot take up a socialistic organ that one does not find therein a gibe or a sneer directed towards the profession. In a very well known British weekly, the editor of which is considered to be quite in the front rank of literary persons, a venomous and inaccurate sketch of the life and work of Koch appeared soon after his death. It stated that he was chiefly known as the discoverer of tuberculin, a remedy which although now discredited had wreaked much harm. When an editor of fame can allow such stuff to be published in his paper, no surprise can be felt when the lesser lights follow in his footsteps. However, the editor in question is not known as a socialist but as an advanced radical. Bernard Shaw has ofttimes flouted medical men and has attempted to raise a laugh at their expense by means which, if not unfair, have at least been open to suspicion. However, it is thought that as poseur, farceur, and philosopher Shaw has shot his bolt and that in future his remarks will not be received with the open-mouthed admiration which has greeted them up to the present. Nevertheless, the fact remains that socialism and medicine do not assimilate. The *Medical Press and Circular* of June 15 refers to the teaching existent among socialists in regard to hospitals. One of the lessons from the "Red Catechism" used in the socialistic Sunday schools, sets forth that in hospitals students and doctors make experiments upon poor patients in order that they may sell the knowledge thus gained to the rich. Therefore, the poor must avoid hospitals. Further it is stated in the *Social Democrat* that "in spite of the doctor being paid to cure disease, he actually profits by its continuation, and his economic incentive is to reverse his *raison d'être*." It is argued that the system of payment makes unscrupulous practices possible and, in short, that a doctor's trade consists in preying cruelly upon suffering and weak humanity.

Direct and Anaphylactic Toxicity of Hydatids.

For a long time in the history of a case of hydatids of any internal organ the effects are purely local and mechanical, due to pressure alone. Late in the disease, however, there comes a time when a species of slow poisoning develops, causing a cachectic condition. Earlier, in any case, there may supervene sudden severe poisonous symptoms due to the opening of the hydatid sac by trauma, the contents of the sac being suddenly thrown into the circulation. It is found, however, that this fluid is not always poisonous, and if the contents of an hydatid cyst be injected into animals no toxicity is shown in many cases, while in a few it results. L. Boudin and Guy Laroche, in an article in *La Presse Médicale* for May 4, 1910, explain this state of things as due to anaphylaxis. The small amount of poison that is slowly absorbed from the closed sac makes the system of the patient unduly sensitive to the toxin of hydatids, and a sudden dose of these poisons in the circulation causes symptoms of severe poisoning and even death. A large number of eosinophile cells are found at the periphery of a hydatid cyst, which probably form in the pericystic tissue as a result of the dialyzation of poisons through the walls of the cyst. The new researches with reference to anaphylaxis will doubtless explain a number of previously not understood phenomena in disease, for example, the idosyncrasies in respect of food-poisoning from which some persons suffer. Cyclic vomiting seen in children may perhaps be explained in the same way.

News of the Week.

Ambulance Accidents.—Two more accidents to ambulances responding to calls, one in New York, the other in Jersey City, revive the question whether more serious trouble is not caused by the rapid driving through the city streets than is prevented by the prompt attention. In the first case, a Bellevue Hospital ambulance was struck by a recklessly driven express wagon and completely wrecked, the surgeon, the patient, and the driver all being rendered unconscious. In the second case, an ambulance from the Jersey City Hospital collided with a trolley car and the surgeon was badly bruised and cut. Neither the driver nor the patient was hurt. The driver of the ambulance charges that the gong of the trolley car was not rung, while the motorman makes a similar complaint against the ambulance.

Accident Prevention.—The National Association of Manufacturers has recently appointed a commission to study the prevention of accidents and the operation of industrial indemnity insurance in Europe. The commission believes that fully 50 per cent. of industrial accidents are preventable, and will pay especial attention to this subject, visiting the museums of safety devices in various foreign cities.

Scarlet Fever in a Home.—The Pelham Summer Home, used as a fresh-air retreat for New York children, was closed recently by order of the Board of Health because of an outbreak of scarlet fever among the inmates. The health officer will enforce a six weeks' quarantine.

Inspection of Dairies.—Acting under the supervision of the State chemist of Michigan, sixteen chemists will tour that State during the summer

months inspecting the dairies and testing the milk produced and supplied to the large cities. The cause of impurities in the milk will be determined and the dairymen advised as to means of correcting the evil. The regular State inspectors will follow them up closely, and where dairymen have failed to comply with the directions given by the chemists, their cases will be referred to the State Commissioner. It is hoped that a large reduction in infant mortality during the summer may be the reward of the experiment.

Ice Cream Cones.—Two seizures in New York within a few days of large numbers of ice cream cones show the operation of the pure food law in a new direction. On the second occasion four and a half million cones were seized on one of the North River piers en route to Galveston, and condemned as containing boric acid and unfit to eat. Government officials say that their investigations into the cones served with ice cream to the small boy on the street for a penny show that sawdust, shavings, and even wrapping paper have entered into their composition.

Crocker Cancer Fund.—The sale of the estate of the late George Crocker at Darlington, New Jersey, has been announced. This is one of the two pieces of property which Mr. Crocker left to Columbia University with the direction that the proceeds of their sale constitute the Crocker Fund for Cancer Research. The price paid for the estate is said to be about one million dollars. The second piece of property consists of Mr. Crocker's town house with its contents.

City Birth Rate High.—During the month of June the number of births in New York State was 16,760, of which 10,352, or nearly two-thirds, were in New York City. The total number of deaths in the State was 11,901, of which 6,323, or only a little more than one-half, occurred in New York City. In other words, in New York City the excess of births over deaths was 4,029, while in all the rest of the State the excess was only 830. Deaths due to violence numbered 769, of which 34 were homicides and 137 suicides, and 135 were due to railway accidents. Old age was given as the cause of death in 161 cases.

Diphtheria on Ward's Island.—The Manhattan State Hospital for the Insane on Ward's Island, New York, has been under quarantine for a couple of weeks owing to an outbreak of diphtheria among the patients. It is thought that the disease was carried to the Island by one of the employees from whom it spread until sixty patients were ill with the disease, in addition to a number of suspected cases. Although the first patients developing the symptoms were removed to the Willard Parker Hospital, the spread was so rapid that it was feared the hospital would be overcrowded, and the Manhattan Hospital staff undertook to care for those stricken. A prompt and rigid quarantine has been effectual in stamping out the infection, and careful treatment has limited the number of deaths to one.

Dr. W. W Hawke has resigned as Chief Resident Physician in the Philadelphia Hospital for the Insane, to accept the position of superintendent of the State Hospital for the Insane at Warren, Pa.

Chattanooga Medical School.—At a meeting of the executive board of the University of Chattanooga on July 12 it was decided to suspend the medical department of that institution. While the action was based upon several reasons, the chief one, it is asserted, is that the university has no endowment for the medical department and finds it impossible, therefore, to provide the equipment or maintain the standard necessary to place it in the front row of medical colleges to which it aspires.

University of Pennsylvania Medical School.—The trustees of the University of Pennsylvania announce the following changes in the personnel of the Medical Faculty, to go into effect at the beginning of the session in September, 1910. Dr. David L. Edsall has been transferred from the Chair of Pharmacology and Therapeutics to the Chair of Theory and Practice of Medicine made vacant by the resignation of Dr. James Tyson, and the former chair will be filled by Dr. A. N. Richards, now professor of pharmacology in the Northwestern University Medical School. The endowment of a Chair of Physiological Chemistry has been made possible, and Dr. Alonzo Englebert Taylor of the University of California will be the first incumbent. Dr. Richard M. Pearce of the University and Bellevue Hospital Medical College of New York has been appointed Professor of Pathology, and will also head the department of research medicine recently established by an endowment of $200,000. Dr. Allen J. Smith, the present dean of the Medical School, will be the occupant of the new Chair of Comparative Pathology, and will also be at the head of the newly instituted courses in Tropical Medicine. Dr. Paul Lewis, until recently connected with the Rockefeller Institute of New York, has been elected Assistant Professor of Pathology, and will have charge of the laboratory of the Phipps Institute for the Study, Prevention, and Treatment of Tuberculosis, now an integral part of the University.

The American College of Medicine of St. Louis, Missouri, announces the appointment of Dr. Frederick A. Baldwin (University of Michigan, Medical Department, 1898) as Professor of Pathology and Clinical Medicine. Dr. Thomas G. Atkinson has been elected Professor of Neurology, and Dr. George M. Heath, Professor of Physics and Physiological Chemistry in the same institution. The college opens on September 6.

"Death Avenue."—In response to the request of the Mayor of New York, the Public Service Commission of this city has submitted tables showing the number of persons killed and injured on the surface railway lines of the city as compared with number of accidents on the street tracks of the New York Central Railroad below Sixtieth street. The figures are for the consideration of the Board of Estimate which has taken up the agitation for the removal of the railroad's tracks from the city streets, particularly Eleventh avenue, which has long been known as "Death Avenue." The report shows that the number of casualties on the trolley lines is far greater than those on the Central's tracks. During the first six months of this year there were eight fatal accidents on the trolley lines and only one on the Central's; in 1909 forty-three persons were killed on the trolley tracks and eight on the Central's. While it was to be expected that the accidents on the combined trolley lines would exceed those on the Central's Eleventh avenue tracks, since the mileage of the former is so much greater, yet it is doubtful whether the proportion justifies the exclusive application of the name "Death Avenue" to Eleventh avenue. It would seem that almost any of the streets on which the

trolley cars run might compete for the distinction. The lower figures for the first six months of 1910, however, hold out hope for the future.

Waterless Hospital.—It is reported that the Government Hospital for the treatment of tuberculosis, at Fort Stanton, New Mexico, may have to be abandoned because of the failure of its water supply. The hospital, which is under the jurisdiction of the Public Health and Marine-Hospital Service, had until recently an abundance of water, but the supply has, it is said, been virtually cut off by the action of a railroad in the vicinity which is piping the water to a point thirty miles beyond for use in locomotives. The Secretary of the Treasury has been informed that unless some means of supplying water is found the hospital, in which the Government has invested nearly a million dollars, will have to go out of commission.

The American Public Health Association will hold its thirty-eighth annual meeting in Milwaukee, Wis., September 5 to 9 next. Representatives from many of the national organizations working in the interest of the public health have been invited to be present and to discuss methods for the correlation of the work of such organizations, and for cooperation with a view to increasing efficiency and economy. Sanitary engineering will occupy a conspicuous place on the program. This Association is the oldest national sanitary organization in the United States. Its membership extends over the United States, the Dominion of Canada, Mexico, and Cuba. Information concerning it can be obtained by addressing Dr. Wm. C. Woodward, Secretary, Washington, D. C.

The Fifth International Congress of Obstetrics and Gynecology will be held under the patronage of His Majesty, the Emperor of Russia, at St. Petersburg, September 22-28, 1910. The Russian Committee on Organization, representing every part of the Empire, has effected an organization with Prof. Dem. d'Ott, President; Prof. P. Sadovski, Secretary-General; Prof. H. Zamchine, Treasurer. The special questions to be considered by the Congress are: (1) "Cesarean Section," by Baum, Brandt, Doleris, and Routh. (2) "Non-Operative Treatment of Cancer of the Uterus," by Mangiagalli, Betrix, and Meyer. (3) "Comparative Value of the Different Procedures in the Treatment of Displacements and Deviations of the Uterus," by Schauta, Westermark, and Hofmeier. (4) "The Vaginal Route in Accouchement and Gynecology," by Martin, Jung, Treub, and Wertheim. (5) "Influence of the Nervous System in the Origin and Control of Uterine Hemorrhages," by Macnaughton-Jones, and others. The registration fee is $5.25, payable before the meeting to the chairman of the respective National Committee, through whom cards of admission and all information relative to the Congress will be forwarded. Contributions to the program are subject to acceptance by the Executive Committee of the Congress, to which titles will be forwarded by chairmen of the respective national committees. The time limit on formal reports is 20 minutes; on special communications, 15 minutes; on remarks, 10 minutes. A résumé of all communications accepted under the rules of the Congress, if furnished by authors, will be translated and published in the different languages in advance of the meeting. All the modern languages will be permitted, but reports and discussions submitted in any one language will be translated into the other languages for publication in the Transactions. The committee for the United States is as follows: Charles A. L. Reed (Chairman), Cincinnati; Robt. T. Morris, New York; Howard A. Kelly, Baltimore; Lewis S. McMurtry, Louisville; Matthew D. Mann (Secretary), Buffalo. An exhibition, for which contributions from all parts of the world are solicited, will be held in connection with the Congress, and will include surgical instruments, ancient and modern; apparatus for the equipment of laboratories, operating and lying-in rooms, etc., plans for obstetrical clinics and gynecological hospital wards; portraits of men who have distinguished themselves in the subjects of gynecology and obstetrics; books on the same subjects; pharmaceutical preparations, etc.

Bequests to Charities.—The Babies' Hospital of New York receives $3,000 under the will of the late Mrs. Margaret A. Bromley, who died recently.

By the will of the late Charles S. Ward, who died recently in Roseville, N. J., the Presbyterian Hospital of New York will receive $10,000 on the death of one of the legatees.

The will of Henry Dexter of New York, who died recently, provides for bequests to a number of charities after the death of his daughter. Of these, St. John's Guild receives $10,000;; the Home for Old Men and Aged Couples, $100,000, and St. Luke's Hospital, $1,000.

New Jersey State Pediatric Society.—The first annual meeting of this society was held at the Hotel Chalfonte, Atlantic City, on June 27, 1910. The officers of the society are: *President,* Dr. H. L. Coit, Newark; *Vice-President,* Dr. Alexander McAlister, Camden; *Treasurer,* Dr. B. Van D. Hedges, Plainfield; *Secretary,* Dr. M. J. Synnott, Montclair; *Council,* Drs. J. Finley Bell, Englewood; Thomas N. Gray, East Orange; Burdette P. Craig, Jersey City; Emery Marvel, Atlantic City, and F. N. Glazebrook, Morristown. At the afternoon and evening sessions the following fourteen papers were presented in addition to the presidential address by Dr. H. L. Coit, on "Factors in the Conservation of Child Life:" "Treatment of Typhoid Fever with Special Reference to the Use of Hydrochloric Acid," Alexander McAlister, M.D. "Acute Nephritis in Children," Arthur W. Bingham, M.D. "The Status of Children's Wards in General Hospitals," J. Finley Bell, M.D. "Some Points in the Diagnosis of Pleuritic Effusion in Infancy," D. J. M. Miller, M.D. "The Relation of Orthopedic Surgery to Pediatrics," Sidney A. Twinch, M.D. "Infant Mortality in Summer, How to Conduct a Successful Campaign Against It," Arthur Stern, M.D. "The Dietetic Management of Children During Sickness," Floy McEwen, M.D. "A Method of Dealing with Illy-Nourished Infants," Francis H. Connecticut State Board of Health.—At a recent meeting of this board the following officers were elected for the ensuing year: *President,* Dr. E. K. Root, Hartford; *Secretary,* Dr. Joseph H. Townsend, New Haven; *Water Supply and Sewage Committee,* Drs. Root, Townsend, and McKenzie;

Laboratory Committee, Drs. Root, Phillips, Wolf, and Townsend; *Director of the Laboratory*, Dr. H. W. Conn. In reviewing the work of the past quarter in the laboratory, Professor Conn stated that 847 samples of milk had been received for examination. He considered the milk supply of the State as a whole only fair.

The Nova Scotia Medical Society held its annual meeting at Yarmouth on July 6 and 7. Officers for the ensuing year were elected as follows: *President*, Dr. James Ross, Halifax; *First Vice-President*, Dr. Kennedy, New Glasgow; *Second Vice-President*, Dr. McLean, New Glasgow; *Secretary-Treasurer*, Dr. J. R. Corston, Halifax. The next annual meeting will be held in Halifax.

The Torrington (Connecticut) Medical Association at a recent meeting elected the following officers: *President*, Dr. Thomas L. Thomson; *Vice-President*, Dr. Abram J. Barker; *Secretary*, Dr. D. P. Platt; *Treasurer*, Dr. George Streit. The following committees have been named: *Executive*—Drs. Thomas L. Thomson, George Streit, and H. B. Chapin; *Literary*—Drs. D. P. Platt, A. J. Barker, and W. E. Hoffman. The association is said to be in favor of a local hospital.

The Spokane County Medical Society has completed arrangements for the erection of a suitable building to be used as a home for the society.

Obituary Notes.—Dr. Mihran K. Kassabian of Philadelphia, Pa., died at the Jefferson Hospital in that city on July 12, as the result of *x*-ray burns. Dr. Kassabian's name must be added to the already long list of those experimenters with the powerful rays whose lives have been the price of their devotion to science. Born in Cæsarea in Asia Minor in 1868, Dr. Kassabian came to the United States in 1894, and four years later was graduated from the Medico-Chirurgical College of Philadelphia. Immediately after his graduation he was made instructor in electro-therapeutics and *x*-ray treatment in the college, a position which he resigned in 1902 to become director of the Roentgen ray laboratory in the Philadelphia General Hospital, remaining in the latter position until his death. The injurious effects of the rays were first noticed in 1902, when the finger nails were affected, and two years later it became necessary to amputate two fingers. The operation, however, did not check the spread of the disease and second and third operations were performed, still without effect. As an authority on the subject of *x*-ray treatment, Dr. Kassabian had been a delegate to many conventions and was the author of several books dealing with electrotherapeutics. He was a member of the American Medical Association, of the Philadelphia County and Pennsylvania State Societies, and of the Roentgen Society and the Medical Club of Philadelphia.

Dr. Walter W. Snyder of London, Ohio, died suddenly on June 26. He was a graduate of the Starling Medical College in the class of 1901, and was 34 years of age.

Dr. Charles B. Richmond of Denver, Col., died at his home on July 1, aged 56 years. Dr. Richmond was a graduate of the Northwestern University Medical School of Chicago, in the class of 1878, and was a member of the American Medical Association and of the county and State societies.

Dr. Thomas R. Newman of Nashville, Tenn., died at his home on July 4, after a short illness, aged 42 years. He was graduated from the Medical Department of the University of Nashville in 1897.

Correspondence.

THE UNION OF MEDICAL COLLEGE AND HOSPITAL.

To the Editor of the Medical Record:

Sir:—In the Medical Record of July 9, 1910, Jacob Gould Schurman, D. Sc., LL.D., President of Cornell University, in an article on "Progress in Medical Education," after dwelling with proper emphasis upon the necessity of medical schools owning, operating and controlling hospitals entirely under the management of the medical schools and subject to regulation by the faculty, makes the following statement: "No first-class medical school in the United States to-day possesses such a hospital of its own." As this statement, coming from so distinguished an authority, may receive general credence, I beg leave to call attention to the fact that, for more than a quarter of a century, the Jefferson Medical College has, to the minutest detail, owned, operated and controlled its hospital. The same board of trustees has charge of college and hospital, both operated under one charter, receives all funds, and disburses all income from both departments.

Election to a clinical chair in the college carries with it a corresponding position on the staff of the hospital, rules for which provide that the "Attending physicians shall consist of the professor of the practice of medicine and of clinical medicine, the professor of materia medica and therapeutics, and the professor of clinical medicine," and the attending surgeons shall consist of the professors of surgery and of clinical surgery," and so on through the entire faculty. The same rule applies to all members of the teaching body including the professor of pathology who is pathologist, and the professor of bacteriology who is bacteriologist to the hospital. The arrangement of clinics in the hospital is made by the faculty without the necessity of obtaining the consent of the house officers of the hospital, and the same is true of ward section work, classes in the operating rooms, and scheduled attendance in the out-patient departments, clinical laboratory and post mortem room.

The hospital also maintains a maternity department of which the medical director is professor of obstetrics. Every clinical facility at the command of the general hospital is available for teaching purposes, and subject to the requirements of the faculty. The curriculum committee of the college may at any time inquire into the facilities of the hospital or submit to the board of trustees requests for organization of a new department to improve the teaching, and so far as I am aware the Board of Trustees has in every instance provided the facilities requested. In other words, the desirabilities upon which President Schurman lays special stress, have been recognized and supplied by the Jefferson Medical College.

In reporting the budget of the Jefferson Medical College the Carnegie Foundation took no cognizance of the fact that in addition to the income from students—no part of which is devoted to the hospital maintenance—the hospital expended (last year) $228,387.07. There were admitted (last year) to the house, 5,199 patients; 9,160 emergencies were cared for in the accident department; 24,812 patients paid 114,702 visits to the dispensaries; 4,041 of the in-patients and all the accident and dispensary patients were available for teaching purposes.

It is well known that there are other medical schools in this country possessing similar advantages.

W. M. L. Coplin,
Philadelphia, July 12, 1910. Medical Director.

POISON IVY RASH.

To the Editor of the Medical Record:

Sir—I recently passed through an interesting experience with poison ivy rash, acquired during a day of strenuous trout fishing. I have had an attack every year for many years, but since boyhood the attacks have been very mild; so I ignored the ever-present ivy this year in my keen interest in the art of catching a few nice trout in a stream that is fished to death. Two days after my return the rash appeared over my left wrist—I scratched it freely and it extended freely to the hand and half way up the forearm. In a few days I realized I was thoroughly poisoned by that despicable vine, so I at once began to experiment with

various remedies for the sake of suffering humanity as well as for my own relief.

I first tried iced cloths squeezed out in a saturated solution of hyposulphite of soda, but I soon lost faith in this. I next tried a saturated solution of borax, but soon changed to lead and opium wash. By this time my face was badly swollen—eyes about closed and a general erythema clearly seen. Now I knew I was in for it, for the typical ivy eruption appeared wherever I scratched, and I certainly desired to scratch everywhere. I realized then that ivy poisoning is a self-limited disease, and that I should help nature as much as possible, so I ordered for myself a milk diet (after a dose of Rochelle salts) and constant attention to the rash, the itching, and the general erythema. I moved my home to the bathroom, and there for a week I had an interesting fight. Talcum powder, carbolic acid ointment (1-30), iodine ointment and camphorated phenol ointment, acetate of lead solution, sulphate of zinc solution and thymol iodide were all tried but soon given up.

I found it necesary to lie in cool water frequently, after which I poured a saturated solution of bicarbonate of soda all over the body. A kind physician suggested an ointment which I used freely all over the face and chest with considerable relief for a day, but the itching and the erythema would "break through," so I finally tried carron oil poured frequently all over the body and more frequently patted over the worst places. This gave such relief that I continued its use till the end—whenever the itching became severe, I rubbed dry bicarbonate of soda into the skin, covered as it was with the carron oil. This seemed to be the best combination—the dry powder rubbed into the itching places would bring relief after the smarting sensation had subsided.

A second kind physician gave me the following prescription which I used with great benefit:

℞

Zinc oxide, ʒii.
Magnes. carb., ʒii.
Thymolis iod., ʒi.
Aquæ calcis, q.s. ad ʒiv.
M. sig: external use.

After three weeks of suffering the rash disappeared, but scratching could easily bring back the typical rash. I certainly was saturated with the poison which left me with three small carbuncles and a good-sized one on the neck—my first experience. In conclusion, I advise physicians to try ice cold compresses—carron oil, bicarbonate of soda and the above prescription in their treatment of ivy poisoning.

New York. Richard Ellis, M.D

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WAR AGAINST TUBERCULOSIS—DISCUSSION ON SYPHILIS—WASSERMANN REACTION—OPTIC ATROPHY FROM ARSENICAL PREPARATIONS—BATTERSEA HOSPITAL—AMERICAN GUESTS—LIVERPOOL TROPICAL SCHOOL—OBITUARY.

London, July 1, 1910.

The war against tuberculosis is going strong. Today the Countess of Aberdeen, whose work in Ireland I have previously described, is to open an exhibition in Edinburgh, where for the coming week the campaign will be vigorously carried on. Among the movements arranged for is an important conference on tuberculosis at which experts from Europe and America are to assist the deliberations which comprise such subjects as the avenues of infection, preventive measures, prevalence in childhood and the working man in relation to the disease. There is to be a special service for the university students and visitors and an address by Professor Osler, a reception by the Lord Provost, magistrates and council of the city, the annual meeting of the National Association for Prevention of Consumption, addresses by distinguished visitors and the inauguration of the Royal Victoria Farm Colony. A full program—to say nothing of the many hospitals and other institutions which those who can attend the conference will desire to visit.

During the month just ended the surgical section (R. S. M.) devoted two sittings to a discussion on the present position of the treatment of syphilis. It was opened by Mr. Ernest Lane, who thought that the decrease in the last 10 years reported in the public services was also observable in the civil population, though there was in increase among hospital patients. He relied on injection in emergencies. Calomel two-thirds grain suspended in oil, at intervals of a week, for 12 weeks was the most potent. Pain was the most common disadvantage (for which reason grey oil was better for routine work) the others being pulmonary embolism, acute mercurialism and local abscess. Soluble mercurial injections were objected to on the ground of frequent dosage being necessary. Inunction was repugnant to most patients. As to duration of treatment he put it at 5 years, which sometimes should be extended to 7 years, as only so could late affections of the higher nerve centres be certainly averted. Capacity to transmit ceased before immunity to nerve lesions was established. The intervals of treatment should be gradually lengthened. He did not think iodipin of much service. Arylarsonates were dangerous.

Dr. Fletcher said serum diagnosis gave him a positive reaction in 30 to 40 per cent. of primary cases. In other cases the results were reliable, but energetic treatment destroyed the reaction, though if stopped too early a positive result would again be obtained. A negative result, confirmed a few months later on, was evidence of cure. Grey oil was the most effective.

Major French extolled inunction and said there was no evidence that arsenical irreparations prevented relapse. Captain Harrison found three calomel injections to commence sufficient, grey oil being substituted for further treatment. Wassermann's original method gave him useful information employed in a roughly quantitative manner.

Mr. McDonagh recommended excision of the primary sore. Mr. Marshall favored the oral method of giving mercury, but Dr. Pernet said "pills and potions" had undoubtedly failed. Calomel injections, he said, were most potent, followed by grey oil. Treatment should be continued vigorously for two years; afterward mildly up to seven years. Iodides suited patients over forty. In mixed infections a vaccine, if a complicating organism could be isolated. Mr. Bayley said there was no reason to look on the disease as surgical, for the pathologist was as much concerned as the surgeon or physician in its treatment. He would make it notifiable and try to isolate and stamp it out.

Mr. Hutchinson was not so convinced as some of the speakers of the value of injections. The iodides were useful, not only in the tertiary, but in some secondary, lesions, *e.g.* intractable ulcers of the tonsils. Further evidence was needed to establish the alleged fact that in congenital cases the Wassermann reaction would not be abolished by intramuscular injections. Nine out of ten, if not nineteen out of twenty, cases could be cured by the oral method. This seemed proved by the occurrence of fresh infection. Arsenic preparations were extremely dangerous. Cases which did not respond to the oral administration were often as obstinate to intramuscular injections.

Mr. Godlee said the disease had, to a great extent, passed out of the realm of surgery; he no longer saw in hospital or private practice the cases he saw ten or fifteen years ago.

Mr. E. Lane, in reply, said he could not accept the extreme view that the oral plan was useless, for the cases treated during the last fifty years did fairly well. Though iodides did not affect the virus, they were useful adjuncts in treatment.

The Wassermann reaction, several times mentioned in the foregoing notes, has also been discussed at the West London Medical Clinic, but only in relation to eye work. Mr. Bishop Harman presented a paper based on forty cases, the pathological examinations having been performed by Dr. Blunt. The patients comprised both adults and children, and Mr. Harman considered the results, added to the evidence in favor of the reliability of the test, a good point, for it was that it entailed no risk and no inconvenience save the abstraction of a few drops of blood. When standardized, as proposed by pathologists, the value of the test would be increased, for it would not only indicate a general infection, but would point to the nature of a given local inflammation.

Mr. McAdam Eccles suggested testing the parents of the patient and their other children. Mr. McDonagh mentioned cases under his care in which the mother and child both gave the reaction.

Another subject mentioned in the previous discussion was the danger of arylarsonates. This point has been confirmed by yet another society, viz., the Ophthalmological, at which Mr. Ernest Clarke related two cases of optic atrophy, which he had no doubt were

caused by the treatment. He therefore urged extreme care in the administration of arylarsonates, the eyes being carefully examined before resorting to them, and as carefully watched during the treatment. The dose must be regulated with regard to body weight and age; he doubted if it would be safe after forty. Disease of arteries, kidneys or liver contaminated it. Colonel Lambkin had used the treatment of which he was the chief advocate, mostly, if not entirely, in young patients. When the limitations and dangers were fully recognized, possibly these remedies may prove as useful as is hoped by many. Meantime, it must be remembered that to the risk of blindness in a fatal disease like sleeping sickness is a very different thing from exposing a patient to such a risk who is suffering from a disease which is amenable to other and well-tried remedies.

Another research expedition from the Liverpool Tropical School of Medicine sailed on Saturday for Malta. This is the twenty-third expedition of the school, and Mr. Newstead goes to investigate the habits of the sandfly with a view to its destruction in the larval stage. The Colonial Office contributes from its Disease Research Fund to the cost of the expedition.

A party of American surgeons landed at Liverpool on Tuesday, and are visiting our hospitals in London and various towns.

Battersea Borough Council has been reported by the Auditor to have gone "beyond the reasonable limits of discretion" in support of the antivivisection hospital. It seems this hospital had the free use of the Town Hall on five days, equal to the total use granted for other philanthropic purposes during the whole year. Horses, vans and charged electric accumulators were also loaned free for demonstrations or processions. Money collected as cloak room fees was given as a donation, and this, but no other, hospital received a subscription out of the Borough funds.

Department Inspector-General G. Jackson, R.N., has died at the age of seventy-eight. He took L.R.C.S.I. in 1854 and joined the medical service of the navy, serving in the Baltic campaign, for which he received the medal. He then saw considerable service on the West Coast of Africa, 1855-1857; in the Abyssinian campaign of 1868, being awarded a medal, and in the Persian Gulf in 1872. He was awarded a Greenwich Hospital Pension in 1905.

Dr. Alfred Francis Thompson, senior anesthetist in the Manchester Royal Infirmary, lost his life on Saturday from an accident. He was motoring home when his car was overturned in a collision. Dr. Thompson was thrown out and sustained a fracture of the skull, and died at once. He was elected to various posts in the infirmary soon after taking his M.B., Ch.B., in 1903, and eventually became senior anesthetist. He leaves a wife and two young children.

The death has taken place of Surgeon-General P. G. Fitzgerald at the ripe old age of ninety. He served in the Indian Mutiny, was present at Cawnpore and the capture of Lucknow, for which he was awarded the medal with two clasps. He retired in 1880.

Mr. Ralph Keyser, Surgeon to the Cancer Hospital, died at sea on the 17th of June, aged thirty-six. He was a St. George's student, and there held various minor appointments after qualifying at the two colleges in 1896. He proceeded to the Fellowship of the College of Surgeons in 1899.

Dr. F. S. Stanwell, late Medical Officer of the East Riding Lunatic Asylum, died on the 26th of June, aged thirty-seven. He was M.D. of Edinburgh, where he was educated, and had been resident Medical Officer at the Royal Infirmary.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 7, 1910.

Hemorrhage from the Kidney.—A general article is written by P. M. Pilcher, who says that before the cystoscope came into use there were certain rules laid down for determining the source of the hematuria. These were the color of the urine, the time of appearance of the blood, shape of the clot, facts learned from irrigating the bladder and microscopical examination of the urine. The author says that when inflammation of the bladder is not present the recognition by the cystoscope of blood spurting or oozing from the mouth of the ureters is unmistakable. Hematuria may arise from trauma and from taking cantharides or turpentine. Of the foods, rhubarb, gooseberries, unripe apples and asparagus may all be followed by blood in the urine. In disease blood may appear in the urine as an expression of intense congestion of the kidney, in malignant fevers and may occur with or without other symptoms. The most common causes of the symptomless form are acute and chronic nephritis, calculus, renal tuberculosis and congestion of the kidney, renal varix, an angiomatous disease of the papillæ renales and papilloma or malignant disease of the kidney. Six clinical histories are given. As to treatment, if the bleeding is due to trauma, expectant treatment is indicated in cases of slight injury in which there is only a moderate or transitory hemorrhage of short duration. Operation is contraindicated when both kidneys are extensively injured, but it is strongly advised when there is progressive, recurrent, or persistent hemorrhage; also when infection has taken place. If due to drugs or diet, remove them and treat as in any acute inflammation of the kidney. In disease no treatment is of any avail in the intense congestion of malignant fevers. If due to nephritis, medical treatment will usually bring about a cure. If conditions persist, decapsulation and fixation of the kidney are indicated. In rare conditions when the disease is unilateral and threatens life the kidney may be removed. In cases of renal varix, nephrotomy is the operation of choice, because it allows a thorough examination of the kidney, and also for the reason that it accomplishes exactly what the operation of ligation does in the treatment of varicosities in other parts of the body—in that it cuts six of the main connecting venous radicles of the kidney and in this way destroys the varicosities. Malignant growths call for removal of the kidney, tuberculosis for removal of both ureter and kidney, calculus for removal and sometimes nephrectomy, nephralgia for renal decapsulation and the fixation of the organ.

New York Medical Journal, July 9, 1910.

Determinable and Indeterminable Factors in the Etiology of Typhoid Fever.—After an elaborate consideration of this subject, L. L. Lumsden offers the following conclusions: (1) Typhoid fever is a disease which is communicable from person to person. The infective agent is effective immediately upon being discharged from the bodies of diseased persons; and anything that will serve to convey the living organisms having the biological features of bacteria of the so-called typhoid bacillus group from the excreta of such diseased persons to the alimentary canal of healthy persons may be a factor in the transmission of the infection. The most common and therefore the most important factors in transmission are personal contact, water, milk, raw fruits and vegetables, raw shellfish, flies and other insects. If there be any as yet unknown factors in the transmission of the infection, their operation is prevented by the same measures which will prevent the operation of the known factors. (2) The factors concerned in the establishment of individual susceptibility to invasion by the infective agent are so far undetermined. It is possible that there is some specific factor so concerned, but the evidence in favor of such a view is very little if at all stronger than the evidence that there are specific factors similarly operative in the causation of diphtheria, tuberculosis, lobar pneumonia and other diseases generally regarded as resulting from bacterial invasion. (3) The bulk of evidence supports the view that the Eberth-Koch-Gaffkey bacillus or "typhoid bacillus" is the essential if not the exclusive factor in the production of typhoid fever and in the adoption of practical measures to prevent the disease this organism may be and at present should be regarded as the specific infective agent in the causation of typhoid fever.

The Quest and Winning of a Vesicle Calculus.—M. W. Ware refers to the diagnosis as made first by the cystoscope, second, by the searcher and, third, by the *x*-ray. He says that the general practitioner when he has a vesical stone to deal with can more readily and sooner get the patient to submit to the introduction of the searcher and thereby pave the way and gain his confidence for a cystoscopy subsequently. Stones that are too small to be revealed by the searcher, hidden in diverticula, their number, size, shape, and all concomitant conditions of the bladder are at once revealed by the cystoscopic searchlight; and though it is beyond cavil that the most painless and harmless and innocuous way of detecting stones in the bladder is by the use of the *x*-rays, there is so much more brought to light by the cystoscope that the use of radiograms could be subordinated and judged superfluous were it not that encysted stones as well as those concealed by an overgrowth of the prostate are invisible with the

cystoscope but revealed by the *x*-rays. Moreover we should have radiograms of the upper part of the urinary tract as well as of the bladder. Particularly imperative is the use of a radiograph of both renal regions, even in the absence of symptoms pointing thereto, where the stone lodged in the bladder is of small size and entitled to be therefore regarded as not autochthonous, but a wanderer from the hinterland of the bladder. A stone, if small enough, may be passed per vias naturales, and hence it led Sir Henry Thompson into sophistry when, in his article, "What Is a Stone in the Bladder?" he laid down the axiom: "Any calculus which can, by any means, be removed entire through the urethra, including one impacted therein and removed thence by the knife, cannot be admitted to rank as a vesical stone."

Vaccine Therapy in Serious Infections of Aural and Nasal Origin.—Two case histories are given by C. Graef and R. B. Wynkoop. Their interest comes from the fact that in one, a clearly established case of septic thrombosis of the lateral sinus, recovery was secured without exsection of the jugular vein, while the other is, so far as can be learned, the first recorded case of meningitis due to streptococcus infection cured by vaccines. Case 1 was that of a boy of 12 years with a suppurative inflammation of the right middle ear of several weeks' duration. Mastoiditis was evidently present and operation was at once done. During convalescence evidences of the inflammation of the appendix came on and it was removed. Pus taken from it showed the *B. coli communis* only. Later streptococci were obtained from the blood and then a stock vaccine was procured and treatment with it begun. Recovery ensued. Case 2 was that of a woman of 24 years who had been operated on for a deflected septum, the nose being packed for 24 hours. At the end of this time she gradually developed evidences of infection which ran on to a well-developed meningitis. Cultures taken from spinal punctures showed the streptococci. An autogenous vaccine was made and under its use this patient, too, recovered.

Journal of the American Medical Association, July 9, 1910.

Radium's Contribution to Surgery.—Robert Abbe says that in epitheliomas of all grades, ulcerated or not, when situated on the skin, a healing and disappearance of the growth promptly follow a correct dosage of radium rays. No such results can as yet be claimed for epithelial cancer of the wet surfaces, although there is a growing hope that its sphere may be increased in this direction. In cancer of the esophagus, stomach, rectum, and uterus, although radium can claim no cures, its use has retarded and given relief, especially as regards cachexia and hemorrhage. The writer reports two cases of pure round cell growth. In Case 1 a tumor had grown on the lower eyelid of a man for a year. It had resisted the faithful application of the Roentgen rays for six weeks, and was still growing. Under radium treatment shrinkage began in two weeks, and in eight weeks no trace of the growth was left. Now, after a lapse of five years, it is impossible to say in which eye the tumor has been. Case 2 was an inoperable renal sarcoma in a child of 4 years. Radium treatment was instituted six months ago, and resulted in great shrinkage of the growth, coupled with an apparent restoration to health. In this case, however, extension in mesenteric lymphatics is now progressing slowly and is uncontrolled by radium. Out of 14 cases of giant-cell growth treated by radium eight remain as cures, though two have died from other causes. The remaining six, though showing characteristic changes, are too recent to report yet as cured. To sum up, it is claimed that "there has been shown the existence of a subtle force latent in radium, resembling that in Roentgen rays, but unlike it and supplemental to it, with specific action for certain cells found in specialized tumors, which causes retrograde degeneration and atrophy.

Purpura from Iodides.—Frank Crozer Knowles, summarizing from his own cases and those reported by others, says that purpuric eruptions caused by the ingestion of the iodides may be divided into two provisional groups: The first includes the extensive petechial, hemorrhagic, bullous cases, which occur in those with organic disease, particularly of the kidneys or the heart, or with a lowered condition of the general economy which makes them more susceptible to the drug, or with a strong idiosyncrasy to the same. The second group includes all cases with a localized distribution, particularly those in which the eruption is limited to the lower extremities, which occur in individuals in perfect health, and can only be explained on the theory of a mild idiosyncrasy. In the hemorrhagic bullous cases the face and extremities were mostly involved, particularly the face and arms. In the petechial type the eruption in a great majority of cases was limited to the lower extremities. The various salts of iodin are all capable of causing a purpuric eruption. The pathologic changes of the skin were noted in the immediate vicinity of the blood-vessels and in the walls of the vessels themselves. Iodin is rapidly absorbed by all mucous and serous surfaces and rapidly eliminated, chiefly by the kidneys and also through the skin itself. The leucocytes play a distinct rôle in the absorption of the drug. Hemorrhagic bullous cases of extensive distribution are frequently fatal, seven out of eleven in this series ending fatally. Petechial, nonbullous cases rarely terminate in death, unless there is marked disease of the heart or kidneys or a very extreme intolerance to the drug.

Excessively High Temperature in a Case of Incipient Pulmonary Tuberculosis.—O. H. Brown reports the case of a patient in the Missouri State Sanatorium in whom the mouth temperature registered 109 to 110, or higher. The rectal and arm temperatures were normal. The observation was made on several different days and with different thermometers, and the writer suggests in explanation that the abnormality may have been caused by the presence of several small sublingual ulcers.

The Lancet, July 2, 1910.

The Tuberculous Gland; Its Significance and Treatment.—R. W. Philip gives the summary of his views from many years' study. He says that suppuration is merely an incident, a relatively uncommon accident in the course of progressive involvement of the glands by tuberculous infection. Far more common is the infiltration in varying degree. The author follows out the course of tuberculous infection, speaks of its relation to childhood, and then passes on to treatment. This should be directed chiefly to the essential lesion rather than to the incidental occurrence. The ordinary surgical treatment is of local and only partial value. Superficial lesions are indeed removed, but the infection is deeply seated in the lymphatic system and only some general measure will meet the emergency. Here the outlook for vaccine therapy with tuberculosis is most encouraging. Dr. Philip details his experience with it, cautioning against too large a dose at first. His conclusions, drawn from prolonged observation and treatment of such cases, are thus given: (1) Watch for the earliest indication of spreading involvement of lymphatic glands in young children. Especially have regard to distribution downward from the extratonsillar gland into the supraclavicular triangle. (2) Regard such a process as of an almost certainly tuberculous nature. If in doubt make use of the tuberculin test. (3) Treat as soon as may be with tuberculin as indicated, at the same time carefully cleansing the throat and correcting faulty environment. (4) If incidentally one or other gland suppurate simply evacuate, continuing the use of the tuberculin.

Points in Favor of Early Operation in Appendicitis.—A. H. Buck says the prognosis in any case of inflammatory appendicitis is absolutely uncertain. If an operation has to be undertaken in advanced stages drainage will be necessary and probably prolonged. If the appendix is not removed the patient lives on the edge of a precipice. If the appendix is removed in the first 24 hours we know where we are. Uncertainty is removed with the appendix. The majority of cases will heal by first intention. Those that do not are certainly such as would need surgical intervention during the attack. Drainage, if necessary at all, is necessary for a far shorter period. If it is necessary, one is only too pleased to have gotten at the trouble so early. The earliest possible knowledge of the exact nature of the case will be obtained. A stock vaccine can be injected if necessary, to be followed within a few hours by an autogenous vaccine. This plan is, according to the author's view, the only way in which to save a case with a virulent streptococcic or other invasion. He insists that an operation in the first 24 hours in cases of inflammatory appendicitis is the only rational treatment.

A Note on the Distribution of Treponema Pallidum in Congential Gumma.—E. A. Shaw refers to studies made in the autopsy room on livers removed from children with undoubted congenital syphilis. A common finding in all the cases is thus described: In a section of this small liver gumma (which was about ⅛ inch in diameter) there was the appearance of a dense black band disposed more or less concentric to the center of the gumma but at its periphery. This band occupied the position of a boundary zone between the healthy liver tissue and the gumma tissue; it was, in fact, the periphery of the gumma. This was seen with a 1-3 inch objective. On applying the 1-12 inch oil

immersion, this black band resolved itself into a dense felted network of spirochetæ which were lying at every possible angle to the plane of section, and overlying each other like handfuls of pins. Proceeding inward from this band toward the center of the gumma there were many more, but proceeding outward from the black band above mentioned they rapidly diminished in number as healthy tissue was reached, till at a distance from the gumma of about a millimeter they were very infrequent indeed. A study of these sections led one to the conception of gumma growth in this type of case, commencing as a small colony of spirochetæ, gradually enlarging in all three dimensions and ultimately developing an encasing capsule, more or less spherical, of thickly agglomerated spirochetæ; then growth proceeding from this peripherally by multiplication of its component individuals, with the spirochetæ inside the gumma multiplying at the expense of the tissue territory thus gradually acquired, until its nutritional possibilities had been by degrees exhausted and it became that half-necrosed area with which we are familiar as the middle of a gumma, and in the center of which spirochetæ were no longer recognizable as typical. If this conception of gumma growth be true, it naturally follows that smears on glass slides made from the surface of a section taken tangentially to the gumma at its junction with healthy tissue should be exceptionally rich in spirochetæ. The author tested this, fixing the smears with methyl alcohol and staining for half an hour with heated Giemsa, and found spirochetæ varying in number from 12 to 30 in every field, instead of, as before, a few in each slide.

Notes on Some Obscure Cases of Extrauterine Gestation.—Three clinical histories are given by T. B. Broadway. In two of them the patients felt "something give way." The first one went into a condition suggesting internal hemorrhage but would not, on recovery from her primary shock, submit to operation. The symptoms returned in a few days, but operation failed to save her, she dying on the third day. In the third case there was a similar history, but operation was refused. The patient gradually recovered, but there were left a fullness over the hypogastric region and a definite bulging in Douglas' pouch and the right lateral fornix. Pieces of membrane were passed, but as the patient had done this during previous menstrual periods a positive diagnosis of pregnancy could not be made. The third case presented symptoms of pelvic inflammation coming on gradually and for some time not appreciated as to their nature. Incision into Douglas' pouch evacuated a macerated fetus of about three months' gestation. This patient recovered. In the first case the abdominal cavity was found full of clots and contained an embryo.

British Medical Journal, July 2, 1910.

Snuffed Powders in Coryza ex Feno.—J. Sawyer refers to a powder mixture made of one ounce of allspice with three drops of oil of eucalyptus used frequently as a snuff. This mixture does not carry the suggestion of mere sneezing but is rather a true errhine producing a substitutive discharge of healthy pituitary mucus in which the materies morbi is killed and washed away. Pimento is a local stimulant and antiseptic and the latter quality is accentuated by the cooperation of the eucalyptus.

Treatment of Chronic Bright's Disease.—W. P. Herringham refers to the usual dietetic and diuretic treatment. He says that he does not hesitate to look upon the excretion of chlorine as more important for prognosis than that of urea, but he cannot speak quite so strongly of the value of the treatment based upon it. The urine always contains some chlorides also and if they are cut off from the food they are drawn from the store in the body and take with them a certain proportion of fluid. Not only should this be done so far as concerns salt itself, but simple articles of diet, as bread and butter, should be made without it and meat and vegetables, if taken, should be cooked without salt. The author says that whatever the blood pressure he has come to regard high pressure as a conservative effort. In old people it undoubtedly brings dangers of its own, especially cerebral hemorrhage. Endarteritis is not the same thing, for it is due to changes in the media and depends chiefly on age. The author is inclined to regard uremia as due to the absorption of some product of renal cells destroyed in the progress of the disease and he compares it to the condition called cholemia in which many cases of hepatic cirrhosis terminate. The symptoms of each are not unlike and the morbid process is similar, also.

Results of the Pancreatic Reaction.—P. J. Cammidge discusses this question and as well the diagnostic value of an analysis of the feces in disease of the pancreas. Pancreatic disease may be divided into (1) acute, (2) chronic, associated with gall stones or local malignant disease, secondary to intestinal disease and gastric or duodenal ulcer, associated with disease of the heart, vessels, or lungs, or finally secondary to metastatic deposits, (3) pancreatic calculi, (4) pancreatic cysts, (5) pancreatic infantilism, (6) malignant disease, and miscellaneous. The various chemical abnormalities found in the urine are discussed in turn. Concerning occult blood in the stools he says that the guaiac and aloin tests are about equal in sensitiveness, both responding to dilutions of 1 to 25,000, and are useful as controls for the simpler and more sensitive benzidine test, which reacts with 1 part in 200,000 of blood. If the benzidine test is negative, it may be concluded that no blood is present, and it is not necessary to proceed further, but if it is positive, it is advisable that the result should be controlled by the aloin or guaiac test. If these are also positive, the presence of occult blood is indicated, but if, on the other hand, they are negative, the presence of occult blood should be regarded as doubtful, and a further examination be made on a future occasion. Hence, a positive benzidine test shows nothing unless corroborated by one or both of the other tests, but a negative benzidine test is proof positive of the absence of occult blood. He has examined 579 specimens of feces with these tests, and obtained evidence of the presence of blood in 89. It has been said that occult blood is found in the feces constantly in malignant disease of the gastrointestinal tract, whereas in simple ulceration it is only met with at intervals. His experience would tend to confirm this, for out of 25 cases of malignant disease of the intestine he found it in 22, in 23 of growth of the stomach it was present in 18, but in 21 cases of duodenal ulcer a positive result was only obtained in 5, and in 16 cases of ulcer of the stomach in 5. In several of the cases of simple ulcer a series of five or six examinations on succeeding days was made before a trace of blood was found. Cancer of the pancreas is very frequently associated with the presence of occult blood in the stools. In 25 of his 38 cases a positive result was obtained. The hemorrhagic tendency that is known to be present in chronic pancreatitis is sometimes shown by the presence of blood in the feces, and in advanced cases serious hemorrhage may take place from the intestinal and other mucous membranes; in 2 of his cases such hemorrhage was the cause of death. This hemorrhagic tendency was the probable explanation of the positive reaction for blood given by the stools of 2 of his cases of chronic pancreatitis associated with jaundice and the presence of gallstones in the common duct, and 4 cases of pancreatitis in which there was no biliary obstruction. He was able to detect blood in the feces of 4 out of the 7 cases of malignant disease of the gall-bladder, and in 2 out of the 6 cases of growth of the common duct that he has examined.

Berliner klinische Wochenschrift, June 20, 1910.

Experimental Syphilis in Rabbits and Apes.—Uhlenhuth and Mulzer find that next to the lower apes the rabbit is better suited for the experimental study of this disease than any other animal. In a recent series of experiments virus both from human and animal sources was inoculated into the rabbit's scrotum, and propagated from one animal to another. The original source of the virus was aspiration-serum, containing spirochetes, from fresh chancres and moist mucous patches, which was inoculated directly into the testicle or beneath the scrotal integument. Animal virus was implanted into the tissues in fragments, into openings previously made with a trocar. Thus material from a rabbit's cornea was passed through many generations of scrotal lesions. The corneal material was itself the result of a long series of inoculations. The virulence seemed to be increased by the continued transmission, as shown by the progressive shortening of the incubation period. The lesions which appeared in the scrotum and testicle occurred in some three forms. First a cutaneous sore, not necessarily in the point of inoculation, the glands being intact. This sore resembled in general a human chancre, appearing in some cases as an erosion, in others as an ulcer with steep borders and an indurated floor and wall. In other cases, the skin remaining immune, either a diffuse or circumscribed orchitis developed. In a third series a fibrous induration of the testicular coverings, especially of the tunica vaginalis, resulted. All these lesions contained the spirochetæ. A slight or limited tendency to general infection was shown by isolated facts—implication of the regionary lymph-ganglia and of the opposite testicle, and by appearance in some cases of circumanal lesions. There is also more or less natural tendency to localization, and to self-limitation, and resolution of the

lesions. A general infection was produced in the ape by intravenous inoculation of material from the rabbit's testicle, a papulocircinate eruption appearing on the trunk and limbs, with general adenopathy.

Aspiration-Drainage of the Pleural Cavity.—Härtel of Professor Bier's clinic has added one more to the numerous devices introduced during the past generation for draining empyema cavities and the like. An ideal apparatus for this purpose must fill three requirements. First, there must be an air-tight isolation of the pleural cavity; second, the derivation of the pus, etc., must be complete, and third, the power of suction must be definitely measurable. Perthe's well-known apparatus comes nearest to filling these requirements, but can only be worn in bed, while the expense is considerable. The author recommends the use of a dentist's rubber dam—a piece 10-15 sq. cm. in area—through which is passed a soft rubber catheter or other drainage instrument. During aspiration, the rubber dam accurately seals up the orifice, and its edges may be fastened to the chest by adhesive plaster. To collect the pus a two-necked flat bottle is used, which should contain from 80 to 200 c. cm. The rubber drainage tube is attached to one orifice, while the tube of an aspirator bulb is similarly made fast to the other orifice. This bulb is of the type used in the "hyperemic treatment" of diseases, and requires no manometer, its aspirating quality having been tested in advance. The so-called Klapp bulb has a negative pressure value of from 100 to 200 mm. of mercury. Its full power is exerted if the bulb is first collapsed to one-half its normal size. The bulb is first applied with a certain degree of collapse, and the amount of aspiration and sensations of the patient serve to control this. When the depression becomes effaced the bulb should be detached and a fresh depression made. The entire apparatus is carried in a sort of linen sling or pocket fixed to the thorax. The apparatus is by no means intended to do away with radical operative procedures, to which it can only act as an accessory; in one case perhaps forestalling an operation and in another serving as after treatment.

Deutsche medizinische Wochenschrift, June 16, 1910.

Treatment of the Hemorrhagic Diathesis.—Amsperger states that true hemophilia is distinguished from all symptomatic forms in being inherited, and inherited through the female members of a family, who themselves may remain immune. On account of the numerous fatalities among bleeders, the females, even if themselves sound, should never marry. Once a bleeder is born he must be constantly protected against trifling injuries, although vaccination is said to be unattended with risk. Stimulants and purgatives are contraindicated. Lime and calciferous substances are believed to be of benefit in that they increase the coagulability of the blood. Hence milk and vegetables should enter largely into the diet and salts of lime may be given internally. The efficacy of gelatin as a hemostatic is believed to be due in part at least to its lime content. Any one of the blood serums used in therapeutics facilitates coagulation of blood when injected subcutaneously. They may be injected once a month in a single dose up to 40 c.cm. and should be varied in kind. This is often necessary, because some of them may set up serum-disease. A selection may be made between horse serum, rabbit serum, diphtheria antitoxin, etc. While a permanent cure is not to be expected, each injection may fortify the patient against bleeding for several weeks. The best results have naturally been obtained in symptomatic hemophilia. It is going too far to claim that this resource is to be depended on in essential hemophilia, but there is no doubt as to its specific power over that condition.

Occurrence of Tubercle Bacilli in the Circulating Blood and the Practical Significance of the Same.—F. Jessen and Lydia Rabinowitsch have studied this subject at the former's Davos Sanatorium. The soundness of the older view that tubercle bacilli were present in the blood only in cases of miliary tuberculosis has been impugned by the alleged discovery by Rosenberger and later by Liebermeister that bacilli are to be found in the blood not only of advanced consumptives, but even in the earlier stages of the malady. It is self-evident that the sanatorium material examined by the authors ought to consist of the latter class; but numbers of advanced cases were also tested as controls. Sediments obtained from venous blood were examined, the technique consisting of steps for obtaining precipitates and the proper staining methods. There were no cultural or inoculation tests made. In a certain percentage of cases either fully formed bacilli or granular débris or both were recognized in the sediment. It would seem from the limited number of observations that the more advanced the disease the greater the likelihood of finding the bacilli, and in an intact condition. The bacteriolytic property of the blood is naturally more in evidence early in the disease. The question suggested by these findings refers to their diagnostic value or absence of the same. If bacilli are likely to occur for the most part in the blood of those already clinically tuberculous, the diagnostic value cannot be great. Hence research should be restricted to suspected and early cases, if practical bearing is to be considered; and, as already implied, the occasional finding of bacilli, perhaps in a disintegrated state, would possess significance in the individual case, but would add nothing to our routine procedures. In the individual case the presence of granules alone might be a rather favorable prognostic, just as the presence of intact bacilli might be construed as unfavorable. In cases with complete negative results, technique having been perfect, the absence of granules would suggest complete bacteriolysis. But it must not be forgotten—and the author's individual cases appear to bear this out—that entry of bacilli into the blood may be due to purely local conditions present in individual lesions in the lung. Thus compression by adhesions of the veins proceeding from cavitary lesions could help prevent the entrance of bacilli into the circulating blood. So also artifically draining a cavity would antagonize a bacteriemia from that source. It is evident that for the present each case must be interpreted for itself alone, and much weight attaches to the exact status of the tuberculous focus.

Present Status of the Wassermann Serum-Reaction for Syphilis.—Stern, who has written at intervals on this subject, has the following to say concerning its latest developments. First, we must look upon the test as corroborative only of the clinical and historical findings. Second, one positive result is not to be too hastily accepted as proving the existence of syphilis. A second test should be made several weeks later. Third, not one of the modifications of the original technique enables us to discriminate with any greater certainty between syphilis and its absence. In cases proved to be syphilitic some of the modifications may add somewhat to the volume of our knowledge of such cases.

Heterochromia of the Iris.—Lutz (Prof. Haab's Zürich Clinic) states that this is a very rare occurrence (1-5 of 1 per cent.), and represents an anomaly of development. The pigmentation of the lighter eye may never have been normal as compared with the other, and this defect may be apparent in the newly born child, or only in after years when the irides tend to become darker (up to the fifteenth year). On the other hand, in some cases the irides were originally pigmented alike and one eye loses some of its pigment. Heterochromic eyes frequently exhibit a tendency to a special form of cyclitis. The coincidence is present in about one-half of all cases. The cyclitis develops in the light eye only, and relatively late, its full development being manifest toward middle life.

Modifications of Glycosuria in Diabetes Produced by Irradiation of the Liver.—Ch. Aubertin and E. Bordet state that irradiation of the liver causes a marked increase in the amount of sugar in the urine. They have irradiated the liver of a patient in whose urine there was twelve grams of sugar per day. The sugar was increased in amount, and the patient dying a few weeks afterward it was found that there was a hyperplasia of the liver corresponding with the hyperfunction during life. In the pancreas there was little change. The increase in the size of the liver was due, not to cirrhosis nor to congestion, but to hypertrophy and cellular hyperplasia.—*La Tribune Medicale.*

Relations of Graves' Disease to Pregnancy.—E. Bonnaire discusses the relations of enlargements of the thyroid to pregnancy. He finds that exophthalmic goiter is six times as frequent in women as in men. A moderate degree of enlargement of the thyroid is normal in pregnancy. Goiter may appear in pregnancy and disappear after labor, it may be permanent, or the elements of Graves' disease may be added to a simple goiter at the time of pregnancy. Graves' disease occurred twice in 30,000 cases at the Lariboisière. This is because marriage is contraindicated in Basedow's disease, as well as pregnancy and lactation. The author reports the two cases observed by him. The dangers to be feared are cardio-pulmonary, and hemorrhage incident to relaxation of the uterus before or after labor. Opotherapy does not give uniformly good results in these cases. In severe cases early emptying of the uterus is advisable. It may become necessary to ligate the arteries supplying blood to the thyroid.—*La Presse Medicale.*

Society Reports.

THE AMERICAN THERAPEUTIC SOCIETY.

Eleventh Annual Meeting, Held at Washington, D. C., May 5, 6 and 7, 1910.

JAMES C. WILSON, M.D., OF PHILADELPHIA, PRESIDENT, IN THE CHAIR.

(*Concluded from page 127.*)

Thursday, May 5—First Day.

High Frequency Currents in the Treatment of Arteriosclerosis.—Dr. THOMAS E. SATTERTHWAITE of New York said that his attention was first called to the beneficial effects of high frequency currents in arteriosclerosis in 1901. Unless one had a static machine, a high frequency coil was best adapted for this kind of treatment. With the use of the static machine there should be a revolution of the plates of at least 350 to 400 per minute. The outsides of the Leyden jars should be connected with a d'Arsonval solenoid or an Oudin resonator. In employing the former the patient was to be connected with both poles by means of a fiber seat, one wire going into it and the other connected with a metal electrode placed in the patient's hand. With the Oudin resonator only one pole was used, a wire running from the binding-post in the resonator to the fiber seat. The Oudin in this way gave the same high frequency on the d'Arsonval, but a much higher voltage. This treatment should last twenty minutes; after which the glass vacuum electrode, attached to either a solenoid or resonator, was applied to the patient, a spark gap being used that would not be painful to him. The treatment should be given two or three times a week for about six weeks, or until the blood-pressure had fallen to the normal or nearly to it. A good method was as follows: The patient is subjected for a few minutes to the high power incandescent lamp, by which means the blood is brought to the surface and a sedative effect produced. Then the static breeze may be given. The sliding holes are pulled apart, so that there will be no spark, the negative side of the machine connected with the insulation platform by the long brass shepherd's crook, and the positive pole grounded. The metal standard is placed near, with the crown over the patient's head, and the negative electricity then streams over his face, so that he feels the breeze. There is also an odor of ozone, which gradually fills the room. This treatment, which is very soothing, and helpful in nervous conditions, is continued for from five to ten minutes, when the patient is subjected to the high frequency current. In this case the plant consists of a resonator combined with a d'Arsonval solenoid, an adjustable spark gap, and a pair of condensers of the Leyden jar type, and the apparatus is operated by a static machine. The patient reclines on a "condenser couch,' which is insulated by glass feet. The cushion has on its under surface a fine metal plate, which runs its entire length and is connected with one pole of the resonator, while the other pole is connected with a vacuum electrode and the fluorescent spark discharge is applied through the clothing to the body. The seance lasts from ten to fifteen minutes. The powerful waves of the static form of electricity, the speaker said, caused short waves of vibration in the capillaries, promoted metabolism in an extraordinary way, and did no harm. In his experience, a diminution in arterial pressure was the regular sequel to the use of the high frequency current, but the seances should not be protracted beyond the time at which the pressure fell to the normal. The high frequency currents alone, however, were not uniformly permanently effectual, though he had found that while the pressure might not always be reduced at each sitting, there was in all instances a progressive decline as the weeks went by. It had sometimes been advised to use the faradic current as an adjuvant. Intestinal atony was often a complication of arteriosclerosis, and this current, applied over the abdominal walls, might be very helpful in relieving the constipation. In addition, he used, according to the indications present in any given case, mercurials, iodides, iron and arsenic.

Further Study of Diabetes as an Infectious Disease.—Dr. ALFRED KING in this paper said that at the last meeting of the American Therapeutic Society he had ventured to express the opinion that diabetes mellitus is an infectious disease, due to the presence of the yeast fungus, *Saccharomyces cerevisiæ*. He recapitulated the arguments on which this opinion was based, and stated that the only link which had seemed lacking to the absolute establishment of the theory was the fact that he had not produced the disease in the lower animals by injecting the fungus, though he had shown that Leo was able to cause glycosuria in dogs by the administration of fermented diabetic urine containing no glucose. During the year that had now elapsed he had not yet had the opportunity, in a somewhat busy life, to experiment on lower animals or complete his investigations; but, with considerable additional experience, he had found nothing to disturb his confidence in the theory or his faith that it would be established. He had now examined forty patients, and had obtained a pure culture of the fungus from the blood of every one with a single exception, that of a little boy of three years in whom the attempt to sterilize and prick the finger excited so much nervous disturbance and resistance that it seemed wiser to desist. In treating an infectious disease he believed that the whole physical condition should be considered; also the methods of treatment which had been found beneficial in the past. The treatment of diabetes should be hygienic and medicinal; it must aim at removing and controlling the injurious effects, as well as the cause. Antiseptics had proved useless for retarding its action and growth or destroying the fungus and the vaccine treatment alone was most effective. This restored the strength and sense of well-being, relieved the thirst, reduced the sugar content of the urine, and checked the polyuria. All this it did by increasing the resisting power and destroying the cause, and its employment twice a week soon brought the opsonic index above normal. He was aware, he said, that much was still to be learned as to the preparation and use of vaccines for treatment of infectious diseases and in the study of immunization, but he believed that Wright's work was epoch-making in medicine. His own work on diabetes had given him increasing confidence in the truth of the theory and in securing still better results. He cited a number of cases, and stated that those taken early had given the quickest and best results.

The Preparation of Thyroid Glands for Use.—Dr. S. P. BEEBE of New York said that the usefulness of the thyroid gland as a therapeutic agent in other conditions than those of the classical myxedema had been demonstrated so thoroughly that the demand for a standard preparation might no longer be ignored. The manufacturers at the present time supplied a variety of thyroid products prepared by different methods, and undoubtedly of differing therapeutic effects. During the last three years he had had many opportunities to compare upon human subjects the effects produced by administration of various forms of thyroid preparations, and from these observations the only possible conclusion was that the human thyroid extract, administered hypodermatically, was by far the best for the human subject. When we gave this we gave a substance ready for instant use, and a comparatively small quantity would act more effectively from the qualitative and quantitative standpoint than a larger quantity of any other kind of thyroid material. These other forms probably acted very largely by stimulating the gland of the individual to whom they were administered. In its effects

upon simple goiter, myxedema, cretinism, athyroid symptoms occasionally found in the later periods of exophthalmic goiter and various metabolic disorders associated with hypofunction of the thyroid, there was no other substance which acted so economically and efficiently as the proteid precipitated from extracts of normal human thyroid glands by acetic acid and heat at 44° C. Therefore, we should use only the proteid obtained by a similar method from animal glands. Accordingly, the original precipitate was washed repeatedly with normal saline by decantation or centrifugation until the wash water was free from biuret substances. It was then dissolved by the addition of a little sodium hydroxide, and the solution filtered through a thick paper mat and again precipitated by acidifying with acetic acid. Heat was rarely required for the second precipitation. The washing process was repeated, and more proteid-like material removed from the precipitated globulin. The final washed precipitate was centrifugated or filtered out and dried at a low temperature, or it might be kept in solution and, after filtration through a Berkefeld, reserved for hypodermatic administration. The prepared protein showed quite as wide a variation in its iodine content as did the fresh glands; and before being used therapeutically it is essential that the proteid should be standardized on the basis of its iodine contents, and a uniform intelligent dosage regulated thereby. For the standard, the proteid obtained from normal human thyroid glands had been selected. The average figures of a large number of iodine analyses of the proteid obtained from normal human thyroid glands by the process described showed that one gram of the purified proteid contained 3.384 milligrams of iodine. After the purified proteid from the animal glands was obtained, the iodine content was determined by the method devised by Dr. Riggs, and, regardless of whether this proteid was richer or poorer in iodine than the standard, it was considered that each 3.384 mgs. of iodine represented 1 gm. of the active thyroid proteid. For the purpose of administration the proteid was diluted with the appropriate amount of lactose, and made up into two-grain tablets by the usual method. Tablets of different strengths were prepared, and 1, 2 and 5 per cent. tablets had been found to give a sufficiently wide variation in strength for all the usual requirements. By one per cent. tablet was meant that one per cent. of the dried weight of the tablet was made up of the purified thyroid proteid according to the standard described. It would be observed that by this method of standardizing and preparing the proteid for therapeutic administration a uniform physiological activity might be expected, regardless of the character of the glands from which the proteid had been obtained. For hypodermatic use, solutions of the proteid in varying strengths, standardized on the iodine basis, had been put up in sealed glass tubes. The products prepared according to the method mentioned had now been employed for about two and a half years in a wide variety of conditions by a considerable number of experienced clinicians; and the results had demonstrated their value to such an extent that he had no hesitation in saying that this method of preparing and standardizing thyroid, giving as it did all of the physiologically active portions of the gland, with none of the toxic, deleterious substances contained in the whole extract, was superior to any method now in vogue.

Friday, May 6—Second Day.

Asthenia Universalis Congenita.—Dr. Charles Lyman Green of St. Paul, Minn., reviewed the characteristic features of the affection, as described by Stiller, and stated that his own studies of it had for the most part fully confirmed the correctness of Stiller's contention. The treatment, he said, was largely a matter of building up the vital powers of the patient, and incidentally he deprecated surgical interference in the treatment of enteroptosis, which was a common practice in the condition. In many instances the physical characteristics are such that the subjects were likely to become victims of tuberculosis unless extreme care was taken.

Dr. Edward D. Fisher of New York said he did not take as unfavorable a view of the prognosis as had been expressed by Dr. Green. Much depended on the management. He was fully in accord with him as to the inadvisability of operation in enteroptosis; an opinion which had been concurred in at the meeting of the American Surgical Society just held in Washington. This applied also, he thought, to many conditions of the female pelvic organs where needless operations had often been performed.

Dr. Alexander D. Blackader of Montreal said the condition described in the paper was far from uncommon. It had not been adequately appreciated, especially in children. He was fully convinced that careful treatment would do much to promote the well-being of the subjects of this affection.

Dr. Oliver T. Osborne of New Haven, Conn., said that almost every person suffering from neurasthenia had some abdominal disturbance. There was one point on which he desired very much to gain information, and that was whether a loose kidney ought to be hitched up or not. It had seemed to him that some patients were not really better after fixation of the kidney.

Dr. Robert T. Morris of New York said he had seen many cases subjected to operation where no operation should have been done. We should carefully separate the cases due to congenital deficiences from those dependent on more recent causes, such as traumatism, etc. Among the stigmata of this affection he thought ought to be classed lack of development of the thyroid and high-arched palate. As to loose kidney, if the organs were pressing upon the pylorus or the vessels of the omentum, or, in short, if it were producing definite symptoms, fixation ought to be practised. Otherwise, this might not be required. The diagnosis was the important thing here.

The President, Dr. Wilson, said nothing could be more timely than this discussion. For twenty-five years the gynecologists and surgeons had been generalizing about operations upon the abdominal and pelvic organs for the relief of certain symptoms, and it had often been found that not only did such operations not afford relief, but actually increased the symptoms. Now the pendulum was swinging back the other way, and scientific physicians were realizing that, while gynecology had its legitimate field, the essential point was the individual examination and diagnosis of each particular case.

Dr. Thomas E. Satterthwaite of New York referred to the frequent relationship found between mucous colitis and neurasthenia, and said that if in such cases proper attention were devoted to the intestine, by the use of high irrigation, etc., it would have a marked effect in relieving the nervous condition.

Dr. A. Ernest Gallant of New York said that if the stomach and colon were prolapsed, and one were pressing upon the other, it was no wonder that we had colitis. The cases which were incurable without operation were those with adhesions which kept the stomach dilated, and in such the patient was very apt to end in an insane asylum if no operation was done. He had now under his care a case of this kind, in which signs of mental aberration had already appeared, and as all other treatment had failed, he intended to operate without further delay.

Dr. Green, in closing, said that as Stiller had pointed out, there was a condition of low vitality, of subnutrition througout the body, and this, he thought, would serve to explain the misplaced colon and the mucous colitis. Deficient development of the thyroid he had not found sufficiently frequent to classify it among the distinctive characteristics of the affection, but arched palate was extremely common.

In regard to operative procedures, he had formerly been very generous to the surgeon, but of late he had found it increasingly difficult to find cases which required operation. If these cases were properly treated it was only rarely that surgical interference was necessary. The essential feature of the treatment was to raise the nutrition, and the weight of the patient constituted the key-note of the whole matter.

Further Uses of Solution of Calcium Creosote in Medicine.—This paper, by Dr. Louis Kolipinski of Washington, D. C., was supplementary to one on this remedy which he read at the preceding meeting of the society. In addition to its use as a surgical fluid, on account of its antiseptic properties, he said it could be applied with great advantage in acute and chronic inflammatory processes of mucous membranes and in different ulcerative lesions of the same. Thus, he had found it of service in catarrhal, follicular, and suppurative tonsillitis and various forms of nasal catarrh, and as an analgesic in laryngeal tuberculosis and cancer of the tonsil or fauces. In syphilis, besides healing the primary lesion, it was beneficial in the sore throat and in necrotic gummatous ulcer of the skin. In dematological practice it would be found to have varied and useful properties. Internally, it was very efficient in the treatment of gonorrheal arthritis. Having referred to its employment in various other conditions, he said that under its use in lupus vulgaris, if the process was broken down and suppurating, the discharge became greatly diminished, and raw ulcerated excavations appeared which were prone to bleed and which were buried under a thick, hard incrustation that repeatedly dropped off and reformed; finally healing and leaving red and very shallow cicatrices, which ultimately turned white. It could not be said that calcium creosote cured lupus, but rather that it destroyed the developed neoplasm. Time and cases had been wanting in which to observe the ultimate results with it. In ulcer of the stomach it might be used, in aid of the milk died treatment, as an antiseptic and antacid. In cancer of the esophagus and stomach, where surgery had failed, it afforded much relief; checking vomiting and obtunding the pain. In connection with the paper several cases of lupus under the calcium creosote treatment were shown.

The Range of Activity and the Untoward Effects of Certain Spinal Analgesics, Based on Two Thousand Administrations.—Dr. W. Wayne Babcock of Philadelphia said that the two thousand cases included all kinds of operations in all parts of the body. This kind of anesthesia should properly be called nerve-root anesthesia, rather than spinal, as it was the nerve roots which were affected. Its safety depended largely on the height of the nerve-roots which it was necessary to narcotize for any given operation. The higher up they were, the greater the danger. It was a true anesthesia that was produced, and not merely analgesia. The delicate thing was to have the solution sufficiently light to affect the sensory nerves, without affecting the motor ones. It could be made lighter by adding 10 per cent. of alcohol to 4 per cent. of solution. By regulating the position in which the patient was placed it was possible to arrest the anesthetic at any point of the spine desired. The speaker considered the doses used by Jonnesco as unnecessarily large, and said that the same results could be obtained from half the doses which he employed. In all operations in the upper part of the body it was necessary to be prepared to perform artificial respiration at any moment. It was not practicable to have the solution of the same specific gravity as that of the cerebrospinal fluid. In the cases embraced in the report various anesthetic agents were employed.

Senile Epilepsy.—Dr. Edward D. Fisher of New York in this paper said that the underlying etiological factor of affection was arteriosclerosis, which distinguished it absolutely from essential epilepsy. The majority of cases coming under his observation were men who had been very active in professional or business life. There might have been few, if any, preliminary symptoms, outside of some fatigue formerly unusual or a slight weakness of memory, until, as out of a clear sky, an epileptic attack took place; perhaps following an exhausting day's work or a heavy dinner. While as a rule the arterial tension was ordinarily rather low in these patients, just preceding the attack it became very high, and was apparently the exciting cause of the seizure. He had not included in this class of cases those of either alcoholic or syphilitic origin. The course of the disease varied somewhat with the course of life followed by the patient after his first attack. The succeeding attacks varied very much in frequency in different instances, and in the intervals the symptoms were not marked, being mostly those of impaired memory, with perhaps some dull headache and dizziness. The arteries involved were probably cortical, and the attacks were no doubt due to temporary occlusion of the vessels—possibly to venous stasis. There might be a localized edematous or serous effusion, but this afterwards cleared up, leaving no trace of paralysis or other impairment. There was probably a general sclerosis of the cerebral arteries, and the general tendency of the disease was towards dementia or premature senility, frequently accompanied by depression. The seizures might at times be very severe and suggestive of apoplexy, and, in fact, they might end in cerebral hemorrhage of the usual type. The differential diagnosis had to be made, especially in the younger cases, from general paresis and cerebral syphilis. It was peculiar how few conditions were present indicative of organic changes in the nervous or arterial system, and yet how marked the clinical symptoms were in this progression towards mental deterioration. Four illustrative cases were cited.

The Routine Use of the Autogenous Vaccines (Bacterins) in the German Hospital, Philadelphia.—Dr. J. C. Da Costa, Jr., of Philadelphia, said that the clinical data of this report related to 94 patients treated during the past year in the inoculation department of the hospital, and the final results were either undecided or equivocal in 44 of this number, still under treatment or but recently discharged. His remarks, therefore, referred to only the first 50 inoculation cases, which could be classified and spoken of with reasonable accuracy. These might be grouped under two headings (1) septicemia; (2) local suppurative lesions. Series I. Septicemia, 17 cases. The vaccine used was autogenous in all instances except two, in which stock vaccine was given in the face of an emergency forbidding delay. Nine were bacteriemias, with 5 deaths, and 8 toxemias (with negative blood cultures), with 3 deaths. Series II. Local suppurative lesions, 33 cases, as follows: Furunculosis, 13 cases; carbuncle, 9 cases; suppurative otitis, 11 cases. Analysis of the foregoing data, correlated with the individual case histories, suggested the following conclusions as to the utility of vaccine therapy in bacterial infections: (1) Autovaccines are of distinct service in the treatment of general septicemia, especially in postoperative cases in which surgical measures have been inoperative. Vaccines are useless in combating sepsis so intense as to stifle resistance, and in such instances the clinical severity of the infection, rather than the identity of the offending bacteria, is the criterion of prognosis. (2) From a laboratory viewpoint the prognosis is better in toxemias than in proven bacteriemias, and the outlook is hopeless when streptococci invade the circulating blood. (3) Autovaccines produce the best results in local infectious lesions. (4) In the class of infections under consideration autogenous emulsions should be used invariably, except when some acute emergency calls for the immediate use of a stock preparation, in the meager hope of tiding over a crisis. (5) The opsonic index cannot be relied upon as an indicator for inoculation and reinoculation, the employment of which should be governed

by the general condition and local signs. (6) The best results follow a moderate initial dose of vaccine, with subsequent doses of greater potency, and intervals of from three to seven days between the inoculations. (7) The longer one's experience with inoculation work, the more must one realize how imperfectly the true scope and limitations of vaccine therapy are understood.

Some Points in Bacterial Therapy.—Dr. F. E. Stewart of Philadelphia discussed the following points: The nomenclature that should be adopted for bacterial vaccines; the diagnostic value of tuberculin reactions in tuberculosis; the value of typhoid vaccine as an immunizing and curative agent; the value of gonococcic vaccine as a remedy and as a diagnostic agent; the therapeutic value of acne-bacterin, staphylobacterin, and staphyloacnebacterin, of stock streptococcus vaccine, and of pneumococcic vaccine; the causes of failure in bacterial therapy; the keeping properties of bacterial vaccines and tuberculins. In conclusion, he called attention to the value of the working bulletin system, whereby manufacturers of new materia medica products might place valuable information concerning these in the hands of the medical profession. This system, if properly employed, would consist of information relative to the manufacture and standardization of the products, together with abstracts from the reports of competent clinical observers, impartially selected from the medical press throughout the world.

The Delayed Menopause; Its Dangers and Therapeutic Indications.—Dr. A. Ernest Gallant of New York said that in women with healthy reproductive organs the menopause should be established abruptly, at an age dependent upon the age at which menstruation had been begun; early, if begun late, and late if begun early. This could be approximately determined and used as a guide to the age at which the menopause might be expected to occur. The menopause was "delayed" whenever menstruation was continued after the "approximate age" and associated with uterine flexion, version, fixation or neoplasm or with tubal disease, syphilis, etc. In delayed menopause the greatest pathological danger lay in the presence or promotion of the growth of fibroid or malignant tumors. The contributory dangers were due to delay: (1) The patient failed to consult a physician, refused examination, or refused operation. (2) The physician delayed examination, failed to diagnose the condition or failed to recognize the importance of early operation; deluding himself and the patient with the idea that the flow would cease, that the fibroid would shrink, unmindful that the grave only could silence and conceal the victim of his delay. The danger signals in delayed menopause were (1) atypical hemorrhage; (2) discharge and (3) pain; signals which, if disregarded, would lead to disaster and death. At the "approximate age" the woman had reached the limit of fecundity; therefore the prophylactic removal of a useless and probably tumor-breeding organ was wholly justifiable, and the one sure method of putting an end to all the threatening dangers. The large number of incurable cases of carcinoma uteri, degenerated fibroids, and malignant cystoma of the ovaries and broad ligaments met with (in some instances occurring as early as the twenty-fourth year) warned us to instruct mothers to inform their daughters of the dangers of delay whenever they suffered from dysmenorrhea, menorrhagia, metrorrhagia, leucorrhea, abdominal tumors, etc.

The Treatment of Parasyphilis in the Light of Recent Research; Paresis and Tabes Dorsalis.—Dr. Tom A. Williams, Washington, D. C., said he regarded these cases as always preceded by a leptomeningitis. In the treatment of syphilis the tendency now was to rely almost exclusively upon mercury. The iodides were of service only in dealing with gummata. This certainly was the practice in France and on the Continent generally. The English, under the influence of Jonathan Hutchinson, still relied considerably on the iodides in the general treatment. The speaker cited seven cases, four of his own and three reported by Charles L. Dana of New York, treated by means of mercurials. His contention was that many incipient cases of paresis and tabes might be cured under adequate mercurial treatment. The important point was that they should be seen early by the neurologist. It was essential that as promptly as possible as large amounts of mercury should be gotten into the system as the patient could tolerate. This should be done by inunction or hypodermatic injection. Administration by the mouth he had not found efficient.

Dr. Edward D. Fisher of New York said the essential point was the matter of diagnosis and this could not be too strongly emphasized. Most of the cases of this kind represented a stage of the disease at which there was still some room for doubt. In Dana's cases the question arose as to the differential diagnosis between cerebral syphilis and paresis. If the condition were that of cerebral syphilis, the patient would be likely to respond to treatment. Many such cases, however, eventually went on to paresis. When a case of paresis was well established, we certainly were not apt to get the good results that the speaker had mentioned. Here was the whole crux of the position. But, as long as there was any chance of affording relief, he was thoroughly in favor of giving energetic antisyphilitic treatment. The tonic effect of mercury was often very marked.

The Present Status of Drug Addictions.—Dr. L. F. Kebler of Washington, D. C., Chief of the Drug Department in the Government Bureau of Chemistry, read this paper, which comprised the results of a series of inquiries sent out to physicians, druggists, and managers of sanatoria. The replies indicated that drug addictions were on the increase in this country. The speaker stated that owing to the strict regulations enforced, these were unquestionably now much less common than formerly in Germany, Austria-Hungary, Holland, and most European countries except England. All advertised drug cures, he said, were a delusion and snare, containing morphine, cocaine, cannabis indica, etc.

Other papers read on this day were: "Bacterins, their Present Status in Therapeutics," by Dr. Noble P. Barnes, Washington, D. C., "The Immediate and After Management of the Puerperant," by Dr. Jesse Stroup of Washington, D. C., and "Hexamethylenamine in the Treatment of Otitis Media," by Dr. Wilfred M. Barton of Washington, D. C.

Saturday, May 7—Third Day.

U. S. P., 1910. How May It Be Constructed?—Dr. Oliver T. Osborne, New Haven, Conn., in opening a discussion on revision of the Pharmacopeia enunciated the following propositions:

1. Let the new Pharmacopeia contain such drugs only as are of positive therapeutic value. If we were in the age of scientific beliefs and research, he could not see how this preamble could be objected to by any one. But the crux of the matter now was to determine what drugs were valueless.

2. When a drug or preparation of a drug is presented that is not official in the Pharmacopeia of 1910, let it be officially declared that the standard of purity and the method of making preparations not recognized in the Pharmacopeia of 1910 be the standard set and the methods of preparation ordered in the last Pharmacopeia in which the preparation was recognized. There was absolutely no satisfactory outcome to be expected from any circulation of requests for approval or disapproval of the various drugs contained in the present Pharcacopeia. The decision for deletion should be left to the judgment of a committee

of five clinical men selected by the U. S. P. Revision Committee. If a deleted drug were valueless, how could a certification to that fact be better made than by omitting it from the Pharmacopeia of 1910? If a deleted drug were really of value it would survive in spite of such deletion, and might be incorporated in the Pharmacopeia of 1920.

3. Let it contain such new drugs as have been proved to be of therapeutic value.

All honest practioners of medicine, he thought, must approve of this recommendation. And here, again, a committee of five clinicians appointed by the U. S. P. Revision Committee should decide what drugs were eligible, and then what drugs were of sufficient therapeutic use to be officialized.

4. Let there be issued a supplement to the Pharmacopeia, in 1915, which shall make official such new drugs as have been proved to be of therapeutic value during the years 1910-1915.

5. Let it give the most simple titles possible to all new drugs, especially synthetic drugs; and an official abbreviation should follow the name of the drug. Every writer of a prescription, and most assuredly every teacher of materia medica, would approve of this. The terrible heart-rending and brain-splitting attempt to prevent all possible advertisement of a proprietary drug had caused a continuous storm of protest over the country, and had forced the ordering of the drug by its proprietary name, much to the profit of the drug promoter.

6. Let it give official approval to the best only of the preparations of the official Galenic drugs, and not officialize the little used and useless preparations of these drugs. As to who should determine which are the most efficacious preparations, this could best be left to the decision of a committee appointed by the U. S. Revision Committee consisting of five clinicians and five pharmacists. Whatever such a committee should decide would be damned anyway, but it was certainly supposable that one or two preparations of a Galenic drug were better than the others, and the best was none too good.

7. Let it not give official approval of all of the known salts (of iron and mercury, for instance), but officialize only the best. This was similar to recommendation 6, and should be decided by the same committee.

8. Let the average adult dose appear after each drug and each preparation of it, not the range of dose, *i. e.* minimum to maximum, as there is no exact under limit or over limit of dose. The dose is enough to accomplish the object aimed at by the prescriber, and all he cares to know is the average dose. It certainly could not be dictated how small a dose a prescriber might order; nor should he be officially limited to a given dose when, in his judgment, with a particular preparation, in a particular condition, in a particular patient, a larger dose was required. There should be no translation of metric to Troy doses. Each dose (and both should be given) should be smooth for each system.

9. As the U. S. P. gives the official titles of drugs in Latin, it should give also the genitive after each title. This would be of special value in teaching the correct writing of prescriptions. It is not always easy to determine the declension to which a Latin noun belongs, or whether it may not be indeclinable.

10. Let the official preparations of a drug be enumerated after the title of that drug. This was an omission from the last Pharmacopeia which had been considered a mistake, and the next Revision Committee would, no doubt, be willing to rectify it.

Later on in the session the recommendations made by Dr. Osborne, with some slight modifications, were formally endorsed by the society and ordered to be transmitted to the new U. S. P. Revision Committee.

Dr. Reynold Webb Wilcox of New York, vice-chairman of the U. S. P. Revision Committee of 1900, said that ten years ago he was in favor of a majority of the recommendations now presented, and he was in favor of them now. While at work on the present Pharmacopeia he had sent out circular letters far and wide, inquiring what drugs and preparations it was desired should be left out and what retained, but the response was so inadequate as to be of no value whatever. He would be glad to see everyone of Dr. Osborne's recommendations carried out, but how could this be accomplished? The thing was all right, but to make the U. S. P. a doctor's book, instead of a druggist's book, was the difficulty.

Dr. Spencer L. Dawes of Albany, N. Y., was of the opinion that the carrying out of these improvements was more practicable than Dr. Wilcox seemed to believe. Not more than one in a hundred physicians possessed a copy of the Pharmacopeia, and the great majority of physicians had no idea what was in it. Of late, however, there had been a very marked awakening of interest in regard to it, and this was largely due to the indefatigable labors of Dr. Osborne.

Should the Pharmacopeia Contain Only Useful and Efficient Drugs?—Dr. N. S. Davis of Chicago answered this question in the affirmative, and said he believed it quite possible for a group of physicians to say authoritatively what drugs were useful. Hitherto drugs had been judged by their use, not their utility. He would like to see also an epitome of the physiological action of the various drugs inserted in the Pharmacopeia, but supposed we could hardly go as far as that at present. Such a thing would be of equal service to pharmacists and physicians. For the good of the physician, as well as of the patient, he was of the opinion that all compounds should be omitted. How many drugs at present in the Pharmacopeia would be affected if only those were admitted which were known to be useful and efficient. He did not believe that more than about twenty-five, though he would like to have a larger number than this left out upon other grounds.

Dr. Howard Van Rensselaer of Albany, N. Y., said the U. S. P. had to be regarded from two points of view, that of the physician and that of the pharmacist. What we ought to have in it was drugs which had a pharmacological action. There might, however, be published in the work a supplementary list of other drugs.

Revision of the U. S. Pharmacopeia.—Prof. Joseph P. Remington, Ph. M., of Philadelphia said that more interest would be taken by physicians in the approaching revision of the Pharmacopeia than ever before—except in the very first years of the life of the U. S. P. when the American Therapeutic Society was aroused from its former state of inactivity—was shown by the fact that one session in its deliberations this year had been devoted to a symposium on matters relating to the revision of the Pharmacopeia. The greatest difficulty to be encountered from the awaking of interest in the Pharmacopeia by physicians was the tendency, especially marked among the younger members of the profession, never to use an old remedy in a prescription if they could possibly think of a new one to answer their purpose. The obliging commercial houses were always ready to take advantage of this tendency to try some new remedy, and the universal hunt for a panacea was always in evidence. While in music, art, and literature something new and fetching must always be provided the masterpieces still lived. To draw a parallel regarding the use of drugs for the treatment of disease seemed like an anachronism, but the law of the survival of the fittest applied to everything. That there was a marked change in the attitude of physicians throughout the country must be apparent to all. The members of the profession were going back rapidly to the use of pharmacopeial prepara-

tions, but the young physician was taking up the subject *de novo*. He knew comparatively nothing about the Pharmacopeia, so that to him the matter was a mystery. He could not understand the why and wherefore of the renaissance. Was not this almost solely due to neglect on the part of the professors in our medical schools, who had for years failed to impress upon their students the necessity for studying and using the ethical preparations of the Pharmacopeia? Progress and research must, of course, ever be carried on if life were desired, but until the time arrived when therapeutics approached a condition of greater exactness and accuracy empirical results must be retained. The controversy which had been going on recently in the medical and pharmaceutical journals, and even in the public newspapers, concerning the scope of the Pharmacopeia had developed two clearly marked views. On the one hand, there was a decided movement to curtail the list of articles to be admitted to the new Pharmacopeia; but a powerful counter-movement had been set on foot greatly to enlarge the list of remedies. Both of these ideas would undoubtedly be ably championed in the coming convention, but it did not need the foresight of a seer or prophet to foretell that neither extreme would ultimately prevail, and that when all were heard, the next Committee of Revision would admit a selected member of the newest articles and would delete many of the older ones which, in the opinion of many members of the medical profession, had outlived their usefulness. The controversies, which had been carried on in an admirable spirit, for the most part devoid of bitterness and hard words, had been of great value in clearing the atmosphere; and both physicians and pharmacists would take up their responsibilities with much clearer conceptions of the magnitude of the task before them; while they would have, to guide them, a vast amount of information, gathered from all sources. While it would be difficult for the next Committee of Revision always to make wisely a proper selection, he had faith to believe that out of the multitude of counsellors there would come wisdom, and that the Ninth Revision of the United States Pharmacopeia would prove to be the best that had been written. After concluding his paper Prof. Remington expressed his gratification at the recommendations which had been adopted by the Society, and said that, coming from such a source, they would undoubtedly have great weight with the Committee of Revision.

Suggestions for the Pharmacopeia of 1910: a Brief Consideration of the Subject in Its Relation to the Federal Food and Drugs Act.—Dr. Francis P. Morgan of Washington, D. C., having stated that by the Act of June 30, 1906, the Pharmacopeia and National Formulary were made legal standards for drug products in the United States, quoted from sections 6 and 7 of the act and regulation 7 of the rules and regulations for the enforcement of the act, which is entitled "Standards for Drugs." He then went on to say that the Pharmacopeia had thus become a legal standard in this country for the strength, quality, and purity of drugs, and it had assumed a close relation to the Federal food and drugs act. With comparatively few exceptions, all drugs bearing the names of preparations described in the Pharmacopeia were required to conform to the standards therein set forth. The exceptions comprised drug products the labels on which contained statements with regard to their own standard of strength, quality, and purity. From this it was evident that in order to secure the highest degree of efficiency for the food and drugs act adequate legal standards were necessary. The standards should be sufficiently high to insure a product of the greatest possible value for the purposes for which it was intended. They should not be unreasonably high, or so low as to fall short of the attainment of the objects in view, and they should be clearly set forth in the Pharmacopeia in language free from ambiguity. Experience had shown that standards which at first sight appeared to be excessively high were sometimes found to be well within the bounds of reason and possibility. Instances of this were seen in the case of asafetida and of hyoscyamus. The three years which had elapsed since the enforcement of the act had afforded an opportunity to test the efficiency of the Pharmacopeia as a legal standard in the case of many drugs, and, as might have been expected, instances had occurred in which the official standards had not proved all that could be desired. It was hoped that this matter would be brought to the attention to the Committee of Revision, with appropriate suggestions for the Pharmacopeia of 1910. The speaker then proceeded to indicate some of the changes which, in his opinion, would be desirable. The proportion of foreign matter permissible in the crude vegetable drugs should be definitely fixed. The quantity of such matter varied with different drugs and in different samples of the same drug, and in most instances its presence was purely accidental. In some, however, the foreign element was intentionally added for the purposes of adulteration. The need of a standard of this character was strikingly seen, for instance, in the case of senna. Owing to the persistent refusal of the authorities to permit the importation of grossly adulterated shipments, the quality of the senna upon the market had very materially improved, but there was no definite pharmacopeial standard by which the line might be drawn between satisfactory and unsatisfactory samples of the drug, so far as inorganic constituents were concerned. A definite requirement with regard to the ash limit would go far toward solving this problem. The experience of the last three years indicated that from the standpoint of the efficiency of the food and drugs act the addition of powdered vegetable drugs was desirable. Colocynth, for example, was defined in the Pharmacopeia as the peeled dried fruit of *Citrullus colocynthis* deprived of its seeds, and in the light of this definition there would seem to be no difficulty in determining what constituted powdered colocynth. As a matter of fact, however, this question had given the authorities much trouble. Samples of powdered colocynth taken for investigation had repeatedly been proved to consist of official colocynth mixed with a variable proportion of powdered seeds, and when the matter had been called to the attention of the dealers they had, in most instances, claimed that the shipment into interstate or foreign commerce of a powdered colocynth consisting of fruit and seeds constituted no violation of the law, because powdered colocynth was not described in the Pharmacopeia, and because, consequently, there was no legal requirement with regard to the quality or purity of this article. Again, it had been shown that the requirements with regard to hyoscyamus should be made more definite in one particular at least. In the official definition of this drug the expression "of mydriatic alkaloids," without further specification as to name or kind, afforded a loophole of escape for those who desired to evade the law. Much of the commercial henbane examined had been found to be adulterated with stramonium, a weed containing mydriatic alkaloids, and considerable difficulty in carrying out the law had been encountered in the case of hyoscyamus so adulterated when the presence of hyoscyamus leaves or tips could be established only with difficulty microscopically or otherwise, as, for instance in fluid preparations and extracts; and especially in instances where the total percentage of mydriatic alkaloids present equaled or excelled the required 0.08 per cent. From this it would appear that in the next Pharmacopeia the requirements relative to hyoscyamus should, if possible, be made more specific as regards the particular mydriatic alkaloids which official hyoscyamus should contain. This suggestion ap-

plied also to belladonna, which was sometimes adulterated with scopola leaves, poke root, and stramonium. The chief difficulty met with in enforcing the law in the case of copaiba concerned the source from which the drug was derived. The Pharmacopeia defined it as "an oleoresin—derived from one or more South American species of copaiba," but, in addition to South American copaiba, many shipments of the African variety, an inferior product, had come to this country, and to distinguish between the two by the tests laid down in the present Pharmacopœia was a difficult matter. Methods by which they could be readily differentiated, however, had been worked out, and the question whether or not these tests should be made official was for the Committee of Revision to determine. As regards balsam of Peru, the object of standardization would be to facilitate the differentiation between the pharmacopeial product and an imitation product which was being offered for import and which could be distinguished from the former only with difficulty by present methods. Other suggestions also were offered by Dr. Morgan.

Officers Elected.—President, Harvey W. Wiley of Washington; *First Vice-President,* Alexander D. Blackader of Montreal, Canada; *Second Vice-President,* Howard Van Rensselaer of Albany, N. Y.; *Third Vice-President,* Robert T. Morris of New York, N. Y.; *Secretary,* Noble P. Barnes of Washington, D. C.; *Treasurer,* A. Ernest Gallant, New York, N. Y.; *Editor of the Transactions,* P. Brynberg Porter of New York.

Next meeting to be held in May, 1911, at Boston, Mass.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE EXPECTATION OF LIFE OF THE CONSUMPTIVE AFTER SANATORIUM TREATMENT. By NOEL D. BARDSWELL. 8vo; cloth; 130 pages. Henry Frowde and Hodder & Stoughtonm, London (Oxford Univ. Press, New York).

STATE BOARD OF HEALTH, Mass., 1908. 8vo; cloth; 876 pages; illustrated. Wright & Potter Printing Co., Boston, Mass.

CONGENITAL DISLOCATION OF THE HIP JOINT. J. JACKSON CLARKE. 8vo; cloth; 92 pages; illustrated; 3/6 net. Bailliere, Tindall & Co., London, England.

THE SCIENCE OF LIVING. By WILLIAM S. SADLER, M.D. 12mo; cloth; illustrated; 420 pages; $1.50 net. A. C. McClurg & Co., Chicago, Ill.

DAS TRACHOM IN OSTPREUSSEN. Von Dr. KÜSEL. 8vo; paper; 80 pages; 1.80 marks. Carl Marhold, Halle, Germany.

DIE AMBULANTE BEHANDLUNG DER UNTERSCHENKELGESCHWÜRE. Von Dr. JESSNER. 8vo; paper; 52 pages; marks, .90. Curt Kabitzsch, Würzburg, Germany.

TREATISES ON FISTULA IN ANO. By JOHN ARDERNE. 8vo; paper; 156 pages; illustrated. Kegan Paul, Trench, Trübner & Co., London, England.

MEDIZINISCHES VADEMEKUM. Prof. Dr. A. POLITZER. 8vo; cloth; 559 pages; $5.00 net. P. Blakiston's Son & Co., Philadelphia, Pa.

SIMON THE JESTER. By W. J. LOCKE. 12mo; cloth; illustrated; $1.50 net. John Lane Co., New York.

A CLASSIFIED LIST OF THE PUBLICATIONS OF KEGAN PAUL, TRENCH, TRÜBNER & Co. 184 pages; paper; 8vo. London, England.

EDUCATION IN SEXUAL PHYSIOLOGY AND HYGIENE. By PHILIP ZENNER, M.D. 12mo; 126 pages. The Robert Clarke Co., Cincinnati, O.

MY PERSONAL EXPERIENCE WITH TUBERCULOSIS. By WILL M. ROSS. 12mo; paper; 64 pages; 50c. Published by the Author at Stevens Point, Wis.

DISORDERS OF METABOLISM AND NUTRITION. By Prof. Dr. CARL VON NOORDEN. Part VIII. 8vo; 103 pages. Part IX. 112 pages. Each part $1.50 net. E. B Treat & Co., New York.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of July 16, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	542	181
Diphtheria	298	24
Measles	344	21
Scarlet Fever	149	10
Smallpox	—	—
Varicella	19	—
Typhoid Fever	45	15
Whooping Cough	20	8
Cerebrospinal Meningitis	3	7
Malarial Fever	—	—
Totals	1,420	266

Electric Treatment of Infantile Paralysis.—A Zimmern and Bordet advocate in the treatment of infantile paralysis after a period of two weeks, the use of some form of electricity to cause contraction of the paralyzed muscles, giving them exercise, and preventing atrophy, and to give the antagonism necessary to the untouched muscles. It also enables the fibers that are in fair condition in the paralyzed muscles to regenerate and hypertrophy, and thus enables them to become once more active. The treatment must be continued for years and must consist of a rather long sitting, in which each muscle is picked out and caused to contract separately.—*Journal de Médecine de Paris.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health, and Marine Hospital Service, during the week ended July 15, 1910.

VENTILATION IN SCHOOLS.*

By W. A. EVANS, M.S., M.D., LL.D.,

CHICAGO.

COMMISSIONER OF HEALTH, CHICAGO; PROFESSOF OF HYGIENE, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL.

Good air and sunlight are necessary at every age period. Probably this need is never greater than during the school years. From seven to seventeen the body is changing greatly. These are the years of plasticity, and at the same time they are the years in which plasticity begins to give way to crystallizing. It is a bad time for the body to get below par. Habits are being established. Eye accommodation is finding itself; the shape of the lens is being established.

There is some reason for believing that the body is charged with a certain number of potential units. When a certain number have been used, repair is possible. There comes a point beyond which repair cannot be established.

If a child is under strain of eye or brain for ten years in the school room, the effect may not be seen at once, yet it will figure in the failures of recuperation which are experienced years afterward. Therefore the school years are tremendously important.

The Chicago schools are heated by hot dry air. In the higher-grade installations the temperature is held at 72° F. The relative humidity is 30. 1800 cubic feet of air per pupil per hour is pumped into the room. In the older installations we frequently find the temperature well over 75° F. and occasionally over 80° F. It has been assumed that because 1,800 cubic feet per pupil per hour is pumped in the ventilation is as it should be. The assumption is rarely justified.

Many clinical observations have demonstrated that school children do not do well in badly ventilated rooms. Dr. A. W. Schram of the Graham School found that such children were prone to infection with the contagious diseases, they had colds, "snuffles," enlarged glands and tonsils. They were mouth breathers; they were pale, flabby, nervous, and subject to headaches. Principal Watt of the same school found that they did not learn readily. They were dull and inattentive.

The windows were raised, the air made fresh and moist, the temperature was lowered to 60° F. and below, according to the outside temperature. The result was that the children were healthier, freer from colds and infections; the "snuffles" decreased. Besides this the children learned faster and better. The principal, viewing it from the pedagogic standpoint, was more impressed even than the school doctor.

As to light: I am strongly of the opinion that the room should be narrow; that it should not be wider than twice the distance from the top of the window to the floor; that the proportion of floor space to wall space should not exceed one to four; that the windows should be so placed as that the light comes from behind or to the side of the pupils, or, rather, that in looking toward their books, the teacher, or the blackboard, they should not have to look directly at a strong light, or their books should not be shadowed so as to strain the eyes.

These effects can be had in various ways. The teacher can be seated at the back of the rooms with the students' backs to the teacher; or shades pulling up from below can make a dark background for the pupils, or the teacher can be so placed in the room as that the wall furnishes a dark background. Blackboards should be treated in the same way.

Believing, as I do, that the removal of air should be as direct as possible, I believe in low ceilings. Between the ceiling and the heads of the occupants is a volume of warm, foul air, which is being chilled and dropping into the breathing zone all of the time. The less space you have, the less foul air there will be to drop back into the breathing zone. I therefore believe in an eight or nine foot ceiling. You will get the operators to heat only a certain volume of air and they will heat the same volume whether the ceiling is eight feet or twelve. By taking off the extra four feet you increase the amount of air which will be furnished in the breathing zone and that is what counts.

But the principal thing which should interest us is ventilation. The harm which is done by bad air falls into two general groups: The quick acting or air borne infections, and the slow acting or air caused conditions. Some illustrations of the former are influenza, common colds and cerebrospinal meningitis, and possibly anterior poliomyelitis, diseases in which the bacteria can be transported considerable distances; pneumonia and tuberculosis, where infections cannot be transported far, and scarlet fever, diphtheria, and measles which can only be transported very short distances.

Illustrations of the latter group are drowsiness, sleepiness, mental hebetude, headache, lassitude, muscular flabbiness, anemia, chlorosis, chorea, abnormal menstruation, mental irritability and exaggerated susceptibility.

The causative agents in the first group in the order of their importance are: Bacteria, dust, humidity, heat, organic exhalations and odors; C O and C O_2, almost negligible.

*Read in the Section of Preventive Medicine, American Medical Association, June 9, 1910, being the fourth of a series of articles on "Ventilation," the articles previously published being: (1) "Harm of Smoke." (Electrification Report to the City Council, Chicago, Ill.) (2) "Ventilation of Street Cars." (*Electric Railway Journal*, May 8, 1909.) (3) "Principles of Ventilation." (Medical Record, May 21, 1910.) Read at the American Public Health Association, Richmond, Va., September, 1909.

The causative factors in the second group in the order of their importance are: Heat, humidity, organic exhalations, C O_2, C O, bacteria, dust, odors. These different elements, with the exception of bacteria, have been so thoroughly discussed that I need not discuss them now.

Many efforts have been made to discover pathogenic bacteria in air. In these cultures saprophytes usually overgrow, and the tests are negative for tubercle and the usual pathogenic bacteria. Conclusion that pathogenic bacteria are not spread by air cannot be logically drawn. Efforts to find typhoid in a general water supply which we are certain is spreading typhoid fever are unsuccessful. Efforts to find typhoid in a milk supply proved epidemiologically to be typhoid spreading have proven fruitless. Nevertheless, we do not conclude that there is no typhoid there.

The mouth has been filled with *Bacillus prodigiosus,* and petri plates have been exposed at varying distances, with quiet breathing, talking, coughing, etc. From this it has been concluded that bacteria can be thrown through the air about twenty feet, and the inference is drawn that that is the limit of the danger zone. The air in front of quiet breathers has been found to have fewer bacteria than when the same air was inhaled. The sum total of all of these observations is an idea that bacteria are not air borne; that they are spread by physical contact. I contend that the inference is unwarranted. Such experiments would have to be impossibly protracted to give results from which conclusions could be drawn.

A person breathes sixteen times a minute for seventy-five years. The absence of pathogenic bacteria from a given cubic yard of air does not prove that there will not be pathogenic bacteria in some of the other yards of air which the man will breathe in his lifetime. And a man only gets consumption once, scarlet fever and diphtheria once; few get pneumonia more than once. More than that: Let us say that only one man in four gets a tuberculosis infection; that is a total three hundred-year period with sixteen breath intakes during each minute of the three hundred years. What conclusion, then, is justified from a determination of the bacterial content of a single cubic yard of air?

Ventilation in schools is necessary for comfort during September and October, and May, June, July, and August in the Chicago climate. In the south we should add April at the front end of the season and November at the rear end. We may say, then, that a study of ventilation resolves itself into a study of ventilation for the months of November, December, January, February, March, and April. It is not of much importance during November and April. January and February are the very trying months.

It has been our observation that school air is too hot and too dry. The temperature has ranged from 70° to 80°; the humidity has been 30 to 40. The dust content has not been high. The odors are objectionable in certain schools in the poorer parts of town and in many schools on rainy days.

The Chicago schools are heated and ventilated as one item. The system used is the Waters. The air is taken in about thirty feet above the ground. It is not cleaned. It is heated to about 110° to 130°, according to the temperature of the outside air, the velocity and the direction of the wind, and the sunshine. It is discharged into the school room at a point above the head of the teacher, by a large opening. It is discharged under an average velocity of 370 cubic feet per minute. It is exhausted near the floor line and usually on the same wall as the inlet. Eighteen hundred cubic feet per pupil per hour is pumped in.

The theory is that the air, being hot and going at a considerable velocity, will rise to the ceiling and flow across to the opposite wall, where it will fall from wall chill and then flow back along the floor to find its outlet. The system is plenum. Should the system work according to theory, the breathing zone of the children at the desks would be dead, and, therefore, polluted, air. As a matter of fact there are many currents and the air begins dropping to the floor almost as soon as it issues. The children situated back in the room do not get a very good supply of air. Much of the air short-circuits from the inlet to the outlet after travelling a short distance in the room.

What is the remedy proposed?

First.—Reduce the temperature of the rooms to a maximum of 68°. This temperature is more bracing. In such a temperature the exhaled air, being hot and moist, will rise right out of the breathing zone and be supplied by purer air.

Second.—Raise the humidity to 60 to 70. No possible objection can be raised to this except that it costs money to evaporate water and the windows will frost when the outside temperature gets to 20° F. and below. The best way to humidify is to introduce a spray of steam into the column of incoming air, if the air is to be pumped in. If the humidity is raised to 60, the pupils will be comfortable with a temperature of 68° F. What is saved on coal, as between 72° F. and 68° F., will more than compensate for the steam which is used to humidify. Some of the frosting of the windows can be prevented by putting a radiator under each window. In certain rare instances a fan throwing enough air against the glass to keep it warm can be used to prevent frosting. But, what harm does frosting do, any way? Its harm is negligible as compared with the harm of over-dry air. It keeps out but little light, and under certain conditions of sunlight will give a mellower, softer light than the unobstructed pane. If the air is brought into the room through the radiators, it can be humidified by pans of water or by some of the patent humidifiers.

Third.—Blow out the air in the room at stated intervals. This is best done by raising the windows and allowing the air to blow briskly through. A change of the air four times an hour will be effected by currents which are so mild that they will not lift bacteria. In consequence the bacterial flora of the air neither decreases nor increases unless it is being modified by animal inhabitation. If, however, the wind blows briskly in and out through windows, the bacterial flora of the air will be reduced 99 per cent. Practically, the way to effect this is to have the teacher throw up the windows when the children go out at recess. When they return they are warm, they have just made heat by exercising. By the time their heat equilibrium has returned to normal the heat equilibrium of the room will have been reestablished.

Fourth.—Decrease the dust content of the air of the school room by having the students at the blackboards use an eraser which is very slightly damp. A piece of cheesecloth fastened over the eraser does well; or the fat can be extracted from an ordinary eraser by ether or naphtha. If the eraser is too moist the board dries slowly.

Fifth.—Introduce the air into the room so as to keep the expired air as much separated from the fresh air as possible. This means direct removal of the air from the breathing zone. This cannot be done if the room is heated and ventilated by the same air. Such air is introduced at 110° F. to 130° F. If it was introduced near the floor and the outlets were placed near the ceiling the hot air would rush straight from the inlet to the outlet and it would be very difficult to prevent great loss of heat. The only feasible thing to do when heating and ventilation is done with the same air is to put the hot air in high and take it out low. The more rational plan is to have the air enter directly from the outside through holes in the walls; these holes to be closed by adjustable diaphragms. The air should pass directly through radiators and be discharged into the room at such a temperature as to maintain a temperature of 65° F. to 68° F.; other radiation to be a hot water or steam gravity system. The radiators should have water evaporating attachments. The air should be introduced in the room at several different points through ducts inside the room, with many openings in the ducts; the exits to be on the inner walls at, in, or near the ceiling; the gathering ducts to lead to the attic with the smallest possible number of turns or angles. In a windy, cold climate, *e.g.* that of Chicago, the duct should lead to a central large exhaust fan in the attic. In a less cold climate, for example, Cincinnati or Louisville, the ducts can lead directly to the roof and open to the outside, surmounted with one of the perflation devices to accelerate suction and to prevent down draft. The philosophy of this suggestion is that when the weather is not extremely cold, and all bends and turns are eliminated from the exhaust ducts, the fans can be eliminated. In a milder climate such as that at Memphis, the ducts can be made to discharge from each room directly to the outside air, the outlet being at the ceiling line. In the far south, *e.g.* New Orleans and Mobile, the windows can be used all winter long, both for inlets and outlets, with this single suggestion, that the radiators be so placed as that they will come a foot or two higher than the bottom of the window. When in cold weather the window is raised six inches or a foot from the bottom, the cold air which enters through the opening will pass through the radiation.

The advantages of such a method over the present method are:

1. The cost of installation will be less than the cost of installation at present employed. The system of ducts is much simpler and the capacity of the fans will be much less.

2. The cost of maintenance will be much less.

(a) On still days the fans will not run at all.

(b) On windy days the fans need only be used to exhaust the air from the rooms on the leeward side. The rooms on the windward side will exhaust without any artificial aid.

(c) The volume of air needed per pupil per hour can be reduced from 2,000 cubic feet per pupil per hour to 1,000 cubic feet per pupil per hour, or even less where the foul air is removed without much admixture with the fresh. In the language of the British Departmental Committee on Ventilation of Factories and Workshops, 1907, "The quantity of air depends on the distribution; and in many cases a relatively small quantity well distributed is far more effective than a large quantity badly distributed."

The clinical observations upon which this paper is founded have been made by the Chicago School Inspectors under the direction of Dr. I. D. Rawlings and especially by Dr. A. W. Schram.

The chemical, bacteriological, and physical examinations have been made by the chemists in the City Laboratory.

The observations on the pedagogic side have been made by Principal Watt.

TENDON TRANSFER FOR CORRECTION OF SPASTIC HAND DEFORMITY.*

By CHARLES N. DOWD, M.D.,

NEW YORK.

The surgery of congenital and acquired anomalies is disappointing; so many normal members are continually in view that they are used for comparisons, the extent of the previous deformity is forgotten, and the patient or his friends express disappointment that surgical skill cannot produce a really

Fig. 1.—Showing usual position of the hand before operation.

normal member. Pictures also are very misleading; advertisements indicate that one can be made to resemble Apollo, Mercury, or Hercules, according to his taste; surgical books are almost as bad, the pictures of operations on such deformities as web-fingers, cleft-palate, and hare-lip indicating that they can easily be brought to normal conditions; and the surgeon feels a keen regret when he learns that the fingers over which he has worked so hard are stiff and misshapen, that even his best cleft-palate operations do not give the ability of normal speech, and that retraction or excessive scar

Fig. 2.—Showing the hand extended (dorsi-flexed) as far as possible before operation.

formation mars the final result in so simple a procedure as the repair of a hare lip.

The operations of tendon transfer have conformed to the general rule in giving disappointment; if certain groups of muscles are too strong

*Read before the Hospital Graduates' Club April 28, 1910.

and others are too weak, it is natural to hope that the strong ones may be made to help the weak ones, so as to restore equipoise, but the adjustment of forces which gives equipoise in hands and feet is a very delicate one, and muscles which have been

Fig. 3.—One year after operation, showing the degree of voluntary extension.

weakened by anterior poliomyelitis or cerebral hemorrhage are very faulty and uncertain structures; hence the skill of the surgeon is seldom able to adjust them, so as to give a function at all comparable to the normal.

To expect to change faulty members to normal ones is clearly an error, but it is also an error,

Fig. 4.—One year after operation, showing flexion of fingers.

probably a much worse one, to fail to appreciate that great improvement can be made in many faulty members; if we compare the results with the previous condition, instead of with the normal member, marked improvement is usually found, and if we can foresee about what improvement may be

Fig. 5.—One year after operation, showing flexion of fingers.

expected, and can explain this to the patient or his friends, we have a field of most useful effort.

Tendon transfer has been more often done in the foot than in the hand, because the muscle groups which are affected there are more easily readjusted and maintained in their new adjustment. The greater part of the surgical literature on the subject therefore refers to the foot and the leg, and a vast amount of it has been accumulated.

There have been occasional records of operations done to relieve the hand deformities, which

Fig. 6.—One year after operation, showing alignment of hand and forearm.

have resulted from cerebral palsy and infantile paralysis; Townsend[1] of this city was a pioneer in the work; in 1900 he read a paper on the subject, now classical, in which he reported some successful cases and referred to others.

In the literature which has accumulated in the meantime the number of cases is not so great as one would expect; an evidence that many disappointments have followed efforts in this field.

Hoffa's report is the fullest which I have found; in 1906[2] he reported the end results on 173 cases of tendon transplantation which had been done in his clinic; among these there were 27 cases for spastic paralysis in the hand. In reference to these cases, he says that he has "regularly improved the hands and that frequently he has adjusted them, so that they were hardly to be distinguished from the normal." He exhibited about 50 cases of various kinds of tendon transplantation before the German Surgical Congress.

Hoffa's Table

Purpose of the Operation	Method of Operation
Relief of pronation spasm.	Separation of M. pronator teres from interna condyle of humerus.
Active supination.....	Hoffa's Pronatorplastic.
	Periosteal insertion of the tendon of the flexor carpi ulnaris over the dorsum of the forearm into the volar radial fascia.—(Frankel.)
Tendinous fixation of the wrist joint in mid-position.	Shortening of M. extensor carpi radialis longior.
	Shortening of M. extensor carpi ulnaris.
	Shortening of M. extensor digitorum communis.
Active dorsal flexion of the hand and active extension of the fingers.	Implanting flexor carpi ulnaris into extensor digitorum communis.
	Implanting flexor carpi radialis into extensor digitorum communis.
	Implanting ext. carpi radialis longior into extensor digitorum communis.
Correction of ulnar abduction.	Lengthening of extensor carpi ulnaris.
Correction of adduction of thumb.	Shortening extensor pollicis longus.
Active abduction of thumb.	Implanting flexor carpi radialis into extensor pollicis longus.
	Implanting flexor carpi radialis into abductor pollicis longus.
	Implanting half of extensor carpi radialis into extensor pollicis longus.
Correction of flexion contracture of elbow joint.	Section of bicipital fascia.
	Section of M. biceps brachii at bend of elbow.
Active extension of elbow joint (compensating for triceps brachii).	Passive insertion of triceps into deltoid.—(Hoffa.)
Active elevation of upper arm (compensating for deltoid).	Implanting trapezius into deltoid.—(Hoffa.)

His method of procedure for the hand was often a complex one, *e. g.* for many of the flexed and

[1]Townsend: *Medical News*, July 14, 1900.

[2]Hoffa: *Archiv. für klin. Chirurgie*, 1906, Band LXXXI, p. 455.

pronated hands, he transferred the origin of the pronator radii teres from the internal to the external condyle, lengthened the tendon of the extensor carpi ulnaris, shortened the common extensors and implanted the tendon of the extensor carpi radialis into their tendons; this has been called

FIG. 7.—Eight and one-half years after operation, showing the hand extended, also showing the growth of the arm.

Hoffa's pronator plastic operation; he gives the above table of the procedures, which he uses to meet various indications.

Recently I have learned the later condition of a patient upon whom I operated for spastic hand paralysis nine years ago, and since the number of cases reported in this country is still small and since the photographs depict the condition in various stages of the procedure, the case is here reported:

April, 1901. The patient's hand showed the condition indicated in figures 1 and 2. Prof. Wm. B. Pritchard, who saw him in consultation, stated that the condition was due to cerebral birth palsy; since birth the arm had been almost useless, at the age of 14 the shoulder dislocation, which was a part of the deformity, had been corrected by excising a part of the joint capsule, and sewing the edges together; following this, the use of the arm had increased somewhat, but the contracture of the hand toward the ulnar side had increased, it could not be properly extended into the line of the forearm, and hung in a position of flexion and adduction; the boy was then 18 years old. The muscles of the arm and forearm were very much atrophied. Since the muscles still had some power, and the condition was largely due to a loss of equipose, it seemed wise to undertake a correction by readjusting the tendons.

The operation for this readjustment was simpler than would have been expected, the flexor carpi

FIG. 8.—Eight and one-half years after operation, showing the fingers flexed.

ulnaris was the most disturbing factor, and when its tendon was cut the hand was liberated enough to permit its proper extension on the wrist, the tendon of this muscle was then brought between the radius and ulna, split into two parts, which were respectively sewed into slits made in the tendons of the extensor radialis longior and brevior, thus using the power of this muscle to aid in extension and abduction, instead of in the opposed motions. The hand and forearm were held in over correction in plaster for two months and then put into a leather splint, with steel supports, which reached from near the elbow to the metacarpo phalangeal joint.

The position was satisfactorily maintained, but he was found to have ulnar paralysis; this was due to the tearing of the ulnar nerve in changing the position of the hand. (If one will flex and adduct the hand so as to bring the pisiform bone close to the cuff and then overextend and abduct it, a gap of more than an inch will exist between cuff and pisiform bone, a greater distance than the nerve would stretch; hence it was torn.)

The nerve was, therefore, sutured one year after the primary operation. The degree of extension and flexion and the correct alignment of the hand just before this operation are shown in the second series of illustrations. He gained good function from the sutured nerve, and wore the leather support for four years. The hand improved steadily

FIG. 9.—Eight and one-half years after operation; alignment of the hand and forearm.

maintaining its position and its power of extension and growing and gaining in strength.

In October, 1909, I was told that it was nearly as large as the other and could be well used in such complicated movements as the use of the knife and fork. The third series of illustrations indicate its condition at that time.

This case has given a much better result than we can usually expect. This result was largely due to the fact that the hand still had good growing and developing power; this power, however, would never have been learned if the operation had not put the muscles in such equipose that they could be used.

I have had only one other opportunity to try the procedure and the result in that case was not satisfactory.

Streptococcus Vaccine in Scarlet Fever.—R. M. Smith says that streptococcus vaccine has some influence in controlling epidemics of scarlet fever. Its use, with proper care, is attended by no harmful results. It should be given wider application in this country to prove or disprove the contentions of the Russian physician.—*Archives of Pediatrics.*

THE USE OF VACCINES, SERUMS, AND THE HISS EXTRACT OF LEUCOCYTES IN THE TREATMENT OF EYE, EAR, NOSE, AND THROAT INFECTIONS.

WITH REPORTS OF CASES.*

By J. G. DWYER, M.A., M.D., C.M.,

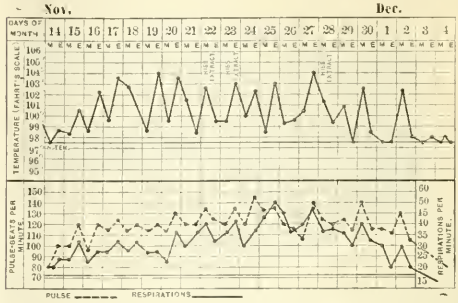
NEW YORK.

CLINICAL ASSISTANT EAR, NOSE, AND THROAT DEPARTMENTS, MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

THE expansion in growth of serum and allied therapy in the last few years, especially following the impetus it received when Wright of London published the results of his work on opsonins, has been so great and has opened up such new avenues for investigation, that the practitioner finds himself literally swamped by a deluge of new scientific terms, new methods of diagnosis and treatment, and by a mass of literature on this important and fascinating subject. It is a matter of no small difficulty for the man busy with his every-day affairs to keep pace with this growth. This is more especially so if he is not trained to some extent in laboratory methods, as the use or administration of these measures is not a simple matter and belongs, not to the province of the clinician alone or to that of the pathologist alone, but rather to a combination of the two. Hence it is that the importance of these therapeutic measures is not more generally recognized; the indications and contraindications for their use are not borne in mind and their limitations are not sufficiently realized. It is with the hope of emphasizing these few facts that I present to you to-night the results of my work along these lines during the last three years. At the same time I take this opportunity of sounding a note of warning against the indiscriminate use of these methods, without due consideration of the suitability or non-suitability of the cases and, what is perhaps more important, the ability of the men to use them intelligently, as more harm than good undoubtedly results from their administration in certain cases. This is not intended as a lengthy dissertation on this subject, but the endeavor has been made to give, in as brief and intelligent a way as possible, from an unbiased point of view, the practical results, reporting the failures as well as the successes and giving the conclusions to be drawn therefrom. In order to understand the criticisms and objections advanced against certain measures, it has been necessary for me to introduce certain scientific terms which are probably not familiar to everybody, but this has been done only where absolutely necessary.

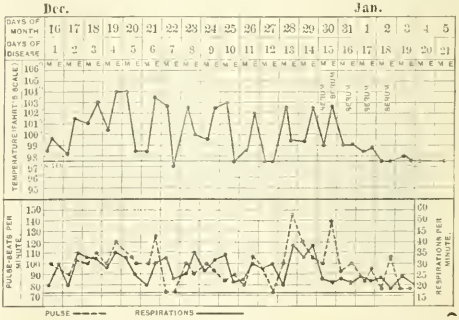
In the first place, I will give a brief résumé of the work done, together with the results. In the majority of cases vaccines were used: In the others, the Hiss extract of leucocytes. The second part of the paper will deal with the relative values of the various measures, the underlying principles, and the indications and contraindications for their use.

Some two hundred or so cases were examined as to their suitability for vaccine treatment. Of this number some 105 were selected, the balance being rejected for various reasons; some, because they were unable or unwilling to come for continued treatment; others, because the causal organism could not be isolated from the mixture of bacteria present in the discharge. Tabulating the cases on the basis of the offending organism, the list is as follows: Tubercle bacillus, 20; stapyhlococcus, 47; streptococcus, 7; gonococcus, 3; pneumococcus, 1;



Bacillus pyocyaneus, 7; Bacillus catarrhalis, 3; bacillus of Friedlander, 3; bacillus of Frisch (*Rhinoscleroma*), 2; mixed infection, 3; bacterium unknown, 9. The list of diseases is not limited to those of the nose and throat, but includes also some interesting general diseases and several cases of eye infections.

The tubercle bacillus cases comprised the following: Chronic tuberculosis of the lungs, 3; of the intestines, 1; of the bladder, 1; cervical glands, 6; larynx, 4; iris, 1; cornea, 1; also 2 cases of phlyctenular conjunctivitis and keratitis and 1 case of episcleritis. The results, on the whole, of tuberculin therapy have been very satisfactory. In all the cases a diagnosis of tuberculosis was made by the various means at our disposal, such as the general physical examination, examination of the sputum and other excreta, the von Pirquet cutaneous test, and the Calmette ophthalmic reaction, also by the reaction to the injection of tuberculin. The kinds of tuberculin used were the bacillus emulsion and the new tuberculin of Koch, known as tuberculin T. R. Of the three lung cases, two were discharged as cured and the third is continuing treatment in another city, still showing marked improvement. The intestinal case was a very instructive one, illustrating well one of the points to be con-



sidered later. The patient was in the pyrexial stage, having fever and symptoms of a systemic intoxication. The opsonic index was considerably over unity. However, injections were started with the idea of still further raising this. Under the treatment, the patient grew rapidly worse, and after a

*Read by invitation before the New York Academy of Medicine, Otological Section, March 11, 1910.

time the injections were stopped. Improvement then took place for a couple of months, but the patient eventually succumbed. This was one of my first cases, and I feel that harm was done. The case of cystitis was markedly benefited. Before treatment the patient had to urinate about fourteen times each night, while now he only urinates twice each night, and his whole general condition has improved and I confidently look for still further progress in his case. The cases of tuberculous cervical adenitis have certainly been most satisfactory, and the results obtained here have amply repaid me for the long time spent in the treatment and the perseverance and constant care which it necessitated. Six cases were treated and all were cured. One patient, in particular, had undergone four operations, and when she came for tuberculin treatment had another mass of enlarged glands and was markedly disfigured by the thickened, unsightly scars at the sites of the previous operations. Under a course of tuberculin the enlargements disappeared, so that the glands were no longer palpable, and, what was quite surprising and the more agreeable, the scar tissue seemed to undergo a certain amount of absorption. This was about two years ago and no recurrence has taken place and the patient is in good condition. In the light of my experience and that of others with such cases, where the condition has not advanced to the stage of caseation or of breaking down, operation is not justifiable, as careful attention to general hygienic conditions and the administration of tuberculin, the dose varying for each case according to the calculated index and the clinical symptoms, will often suffice to save them from the mutilation of the often unsuccessful surgical measures which are now resorted to. Even in cases of caseation and where breaking down is inevitable, a course of tuberculin preceding and following the operation will be of great benefit. The four cases of laryngitis were instructive. The first was primary in the larynx, that is, primary in that no other lesion could be made out. This case was fairly well advanced, but responded to the treatment and was cured. The second case had a demonstrable lung lesion in addition to the local lesion. Marked improvement took place, but the lack of proper facilities at home led me to recommend her removal to a tuberculosis sanatorium, where her improvement has gone on steadily. The other cases had, in addition to the local and lung involvement with tuberculosis, a secondary infection with streptococcus. Neither showed any improvement. Later, judging from the published reports of others who have treated such cases with alternate injections of tuberculin and streptococcus vaccine, the results have been more satisfactory. The remaining cases of tuberculosis were all cases of eye infections. The case of iritis was interesting. A comparatively large, well-circumscribed tumor mass was present on the anterior surface of the iris and there was a question of diagnosis between syphilis and tuberculosis. The history was negative as to the former and tuberculin was injected on two occasions, not for the purpose of treatment but purely for diagnostic purposes. Much to my surprise the mass began to get smaller, and under continued treatment by injection of tuberculin eventually disappeared. The other cases gave the cutaneous reaction to tuberculin, and in the case of tuberculous keratitis, although the case was not an early one, it quieted down under treatment. Patients with phlyctenular keratitis ceased to have the recurrent attacks which had previously been so frequent. The same is true of the case of episcleritis. These cases are now entirely free from these attacks.

The next series of cases comprises the staphylococcus infections. Here 47 cases were treated and, with one exception, all were cured. The list was made up as follows: General furunculosis, 9; acne, 2; carbuncle, 1; eczema of the auricle, 1; otitis externa diffusa, 3; otitis externa circumscripta, 21; otitis media suppurativa subacuta, 5; chronic tonsillitis, 3; peritonsillar abscess, 1; abscess of the septum, 1. The list may not appear very impressive at first glance, but these cases were all chosen because of their known chronicity and comprised that class which ordinarily does not yield to the other well-known methods of treatment, infection after infection occurring. One case of acne was of fourteen years' duration and every kind of treatment had been tried, time and time again, without relief. This patient has now been entirely free for over two years. The otitis externa cases were of that fairly numerous class which is the despair of the otologist, attacks constantly recurring. All these yielded readily to treatment with the vaccine. Under the heading of subacute ear cases are placed that large class in which, after the acute infection has run its course, the suppuration continues and eventually becomes of the chronic type. Five such cases were treated: Three ceased discharging, after practically the first injection; in the fourth, the discharge became much less in amount, and then the patient ceased to report; the fifth was not benefited. This series was made up, as far as possible, of cases in which the pathological lesion was confined to the mucous membrane, not having yet reached the bone; the reasons for this will be stated later. The eczema in question was a chronic one, situated around the auricle, with often-recurring acute attacks being superimposed on the chronic condition. The organism was isolated from a pustule, present during one of these acute attacks, with very satisfactory results. The peritonsillar case was one in which the abscess had been evacuated by surgical measures some months before, but the suppuration continued, becoming of the chronic variety, the cavity filling up with pus, discharging, and again refilling. Two injections sufficed to clear up this condition. The abscess of the septum was also of this variety, essentially subacute or chronic, but one injection of 500 million was thoroughly effectual. With regard to the tonsillitis cases, some doubts were entertained as to the outcome of the treatment, as, on account of the variety of the bacteria, generally making up the flora in the tonsil, the causal one might not be isolated. In the three cases in question, however, the staphylococcus was found in such numbers that it was undoubtedly the causal one. These were cases of chronic tonsillitis, with several acute attacks occurring each year. The treatment here was eminently successful, the chronic or subacute condition cleared up, and during the last winter the patients were entirely free from the acute attacks, this being the first winter in years that they escaped.

Seven cases of pure streptococcus infection are reported, five being cases of postscarlatinal suppurating ears and two of chronic dacryocystitis. Four of the ear cases ceased discharging after varying periods, the fifth remaining the same. Both cases of dacryocystitis were discharged cured.

The next subdivision comprises three cases of infection with the gonococcus, the first being a very

obstinate case of gonorrheal arthritis, which had resisted all forms of treatment. Cure was obtained very rapidly here, although the patient himself had given up all hope of ever being well again. The second was a case of chronic gonorrhea. Here from an examination of the case it was decided that the staphylococcus was playing more than a passive part in keeping the condition active; accordingly alternate injections of the latter and of the gonococcus were used, with thoroughly satisfactory results. The third case was one of conjunctivitis, complicated by ulcerative keratitis; the progress of the disease was quickly arrested and I think the involvement of the cornea was hence much less.

Only one infection with the pneumococcus was under treatment, a case of serpiginous ulcer of the cornea. In the scrapings from the cornea this organism was isolated in pure culture. This ulcer had been repeatedly curetted and cauterized to no avail and then a vaccine was made. Immediately following the use of the vaccine, the process started to subside and soon became quiescent. The treatment in this case certainly cut short the course of the disease and saved the balance of the cornea and in all probability, the eye itself.

Friedlander's bacillus was found as the causal factor in three cases of chronic nasal catarrh. These were of that type in which constantly recurring acute exacerbations were added to the ever-present chronic condition. The improvement in all cases was marked: the chronic condition was much alleviated and the acute attacks could be easily aborted by one injection, given just as the attack was threatening. Here I have also placed three cases of chronic suppuration of the accessory cavities of the nose. These were of very long duration, years in all cases, and the organisms isolated were the bacillus of Friedlander, the streptococcus, and the staphylococcus, all being present in about equal numbers. As in the cases of chronic catarrh just mentioned, the first-named bacillus was found as the causal factor, and as in many other nasal chambers examined, this was found so constantly, it was arbitrarily assumed that this was the causal organism and that the other two organisms were accidental or secondary infections. Treatment was accordingly started on this assumption and pursued for some time. The nasal catarrh, accompanying the sinus condition, cleared up, just as in the cases of straight catarrh, but the sinus condition remained as before, and in the course of some few weeks or months the nasal chambers were reinfected from the sinus. These results, although rather unsatisfactory, are not discouraging, as very great relief was afforded for weeks at a time, and also because the test was a very rigid one, as will now be explained. In the first place, drainage was not secured by operation, and it was purposely endeavored to do without operation, trying to open up the natural passages, according to the method of Wright, namely, irrigating the nose thoroughly and at frequent intervals with a solution of sodium citrate, to promote, if possible, the absorption of the occluding tissues. Nothing much was expected from this, but it was given a trial. Other reasons for failure lie in the fact that a very necessary, and, in fact, indispensable condition, may not have been complied with, that is, certainty as to the causal organism. In spite of these comparatively negative results, I feel that under proper conditions as to drainage and isolation of the proper pathogenic organism, this form of treatment will have a large share in the future.

The next series is also very instructive and interesting, but was not so disappointing, as favorable results were not really expected. It comprises seven cases of suppurating ears in which the *Bacillus pyocyaneus* was isolated and which were treated with a vaccine of this, with negative results in all seven cases. Doubts were entertained from the start, on account of the well-known cultural and pathogenic characteristics of this bacillus, it being one of low pathogenic power, at least for man, generally existing as a parasite, and not being the primary invading organism, but a secondary one. Moreover this bacillus does not rightly belong to the class of organisms producing endotoxins, as the ordinary pyogenic bacteria do, but, on the other hand, it produces a soluble diffusible toxin, pyocyanin, which is easily visible to the naked eye in a culture a few days old. Such an organism would probably therefore call for an antitoxin, like diphtheria, and not a vaccine. In spite of all these factors, however, as this bacillus has been found by others as the only organism in several fatal cases of septicemia, and as it is probably more often a primary factor than is thought, a vaccine was made in each case and used. The results were negative, as above stated. Having in view this fact, it was decided to displace, if possible, this bacillus and to replace it by another parasite of practically no pathogenic action and having no effect on the tissues, as suggested by Metchnikoff and North. A series of cases are now being kept under observation and are being treated by a solution or culture of the *Bacillus bulgaricus*, commonly sold under the name of massolin. The results, so far, have been very encouraging, but the number of cases treated is too small to judge from. Further reports of this investigation will be made in the near future by Dr. Haskin.

Two cases of rhinoscleroma infection with the bacillus of Frisch have been under treatment for the last two years or so, and one is still receiving injections. These are the cases reported last year by Dr. Guntzer and are the first to be treated in this way, so far as is known. Considering the disadvantages we were under in the treatment of these cases, having no precedent to guide us in the dosage and other factors, the results have been encouraging. Cure has not been effected, but the improvement has been marked and the patients, instead of being confined as hospital cases, are able to pursue their ordinary vocations in life. One of the patients, in whom it was necessary to do a tracheotomy, has now gone for months without the tube and his breathing is better than it has been in years. He left recently to take a position in a city in the West.

In comparison with the other methods of treatment recognized as applicable to this condition, such as extensive operation, the *x*-ray, and the use of radium, I think the balance is in favor of the vaccine, if an opinion based on such a small number of cases treated has any value. However, in view of the poor results obtained by any kind of treatment in this slow, obstinate, and comparatively unknown disease, and as the causal bacillus can be so easily grown, treatment by vaccine would seem to be thoroughly rational and would perhaps do more, if our experience were more extensive. Since the treatment was begun the progress of the disease has been stopped in both cases.

There were three cases of infection with the bacillus catarrhalis and with these will be considered three other cases giving the same clinical symptoms,

those of acute nasal catarrh, present in that class of patients who are always "catching cold." In the latter three, the causal bacillus, although easily isolated, could not be classified by name. All cases yielded to treatment; the attacks became less frequent in number and severity, and when an attack threatened, an injection was efficacious in limiting the duration to less than one day. Some of these patients, who used to have a cold or series of colds every winter, have since been free.

Under the name of unknown species of bacteria, I have grouped the last three in the series mentioned above and in addition, four cases of chronic suppurating ears and two cases of chronic dacriocystitis. In these cases the organism isolated was undoubtedly the causal one, but did not fall under any species with which I am familiar. Three of the ear cases cleared up, but the fourth remained as before. The two cases of dacriocystitis were entirely cured.

This completes the list of cases treated. On the whole, I think the results are very satisfactory. It might here be said that all the ordinary methods of accepted or recognized treatment were used in conjunction with the vaccine treatment. Personal hygiene was rigidly insisted on, and in the ear cases local irrigations were kept up. However, in view of the fact that these methods of treatment had been given a thorough and exhaustive trial, in some cases extending over a period of years and in all cases at least for weeks, before the vaccine was used, the results obtained can be fairly attributed to the vaccine treatment.

Some stress was laid on the fact that the choice of ear cases was limited to those in which it was thought the lesion was limited to the mucous membrane. This was in reality a wholly unnecessary proceeding, being due entirely to personal reasons, as the time that could be devoted to this investigation was limited and it was necessary to get quick results, because the majority of cases treated were outdoor cases, and as these patients cannot be expected to come over a long period of time, as is invariably the case, they are one by one lost sight of. A few words might be said about that larger proportion of chronic suppurating ears, in which bone necrosis is probably present. Considering in brief the pathology presented to us in such an ear, we have progressive necrosis of bone up to the point at which the resisting powers of the body are strong enough to stop the advance of the necrosis, that is, we have a line of demarcation formed, just as in the death of the soft tissues or gangrene. The necrosed bone is a foreign body and must be removed. Nature eventually accomplishes this by a slow process of ulceration, taking months to remove it. If the mass is of considerable size, the surgeon can remove this in a few minutes, provided he can do a thorough operation, removing the bone not only macroscopically but microscopically diseased. A consideration of the radical operation shows that the majority of the results attained are not satisfactory, in many cases the suppuration continuing and the after-treatment lasting, from at least a few months in the most favorable cases, to a lifetime in others. Of course there are certain cases that must and always will demand the radical operation, but lately the pendulum has swung back and the radical operation is not being done on every case that presents itself. Any measure, therefore, that offers at least a chance of success, ought to be given a trial. If the causal organism is isolated, and the vaccine treattment tried, nature will be stimulated to form the line of demarcation. The time of treatment will extend over a long period, but even now all forms of treatment of this condition demand months of treatment. It is hoped that a further report on a series of such cases will be made as soon as a sufficient number have been observed.

The Hiss extract of leucocytes was used in nine cases. This was in reality six cases, as the other three were cases that were not suitable to this form of treatment. Of the six cases, four recovered and two died. It will be interesting to give in some detail the history of some of these.

It must be borne in mind that all these cases were ones in which all other measures of treatment had been exhausted, and as a last resort the extract was used, the surgeon in charge of the case feeling that it did not matter much what was done, as the case would terminate fatally. A severer test could not be devised and the results are all the more encouraging because of this fact. The most striking was a case of pansinusitis. G. H., aged 9 years, was operated on, a frontal sinus operation being performed, the anterior ethmoidal cells being removed at the same time. For fifteen days following the operation the temperature ranged between 98° and 105° F., as shown on the accompanying chart. A diagnosis of meningitis was made by Dr. Zabriskie, who found marked general hyperesthesia, deep muscular tenderness, and a well-marked Kernig's sign. The smear from the frontal sinus showed mixed infection with streptococcus predominating. Just before the extract was injected, the temperature was 104.4°, pulse 145, respirations 30. Within twenty-four hours the temperature fell to 100°, pulse to 90, and respirations to 25. The temperature then gradually returned to normal and recovery was uneventful.

The second case was one of mastoiditis and sinus thrombosis, with a general bacteriemia, as shown by the blood culture, long-chained streptococcus being found in the latter. The simple mastoid operation had been performed and the patient had been discharged from the hospital and was attending the out-clinic. On one of the occasions on which he presented himself, he had some fever and was not feeling well. He was admitted to the hospital for observation and after seven days, during which his temperature varied between 102° and 104°, a blood culture showed long-chained streptococcus. Operation was immediately performed and a large clot was found in the lateral sinus. Free bleeding was obtained from the torcular end of the sinus, but rather poor from the jugular end. As the patient was in bad condition, an intravenous infusion having to be given on the table, it was decided not to take out the jugular. The temperature remained down for twenty-four hours, but at the expiration of this period again arose and assumed the septic type. The Hiss extract was then started and the improvement in the general condition was immediately marked, although the effect on the temperature was not so noticeable. As soon, however, as visitors were forbidden entrance the temperature returned promptly to normal. Here, it may be noted that the jugular was not excised, the clot simply being cleaned out as thoroughly as possible.

The third case of this series was also one of mastoiditis, complicated by sinus thrombosis. At the time of operation, the lateral sinus was found thrombosed and filled with a very foul smelling pus. The jugular was accordingly excised. Following

operation, the temperature gradually rose, each day being a little higher than the preceding. Physical examination on the fifth day following operation revealed symptoms of beginning meningitis, the patient also being unconscious and delirious. Immediately following this examination, the Hiss extract of leucocytes was given at regular intervals of twelve hours and the improvement was marked from the very beginning of the treatment. The temperature gradually fell and the great improvement in the general condition of the patient was most marked; the symptoms of the toxemia gradually disappeared, the delirium disappeared within a few hours, and the patient was perfectly rational in twenty-four hours. Three days after the beginning of this treatment the temperature had reached normal and thereafter the recovery was uneventful.

The fourth case was one of mastoiditis, complicated later by sinus thrombosis and lobar pneumonia. This was the first case to be treated by the extract, and the patient was in a practically moribund condition when the extract was given. The history is as follows, and the accompanying chart shows the course of the temperature: Four days after a minor nasal operation the patient developed an acute infection of the left middle ear, together with mastoiditis and eventually came to operation, a simple mastoidectomy being done. Following operation, the temperature was of the septic type as shown on the chart, and on the fifth day patient had a decided chill. The next day a second operation was decided on and on exploring the lateral sinus a large clot was found and evacuated; the jugular was then excised. The temperature continued to be of the septic type, and on the second day the Hiss extract was injected. The patient was *in extremis*, as a pneumonia and pleurisy had developed. The extract was given irregularly, but eventually improvement was noted and convalescence was uninterrupted.

The next two cases are the ones that progressed to a fatal termination. The first was a child, one and one-half years old, and was operated on for acute mastoiditis, the usual simple mastoidectomy being done. The patient was in bad condition, a large subperiosteal abscess being present. Temperature on admission was 101°; immediate operation was done, and following the operation the temperature gradually rose, reaching 105° on the fourth day and 106.5° on the eighth day. The diagnosis was uncertain, as there were very few physical signs to go by. On this day, however, well marked opisthotonos was present and a second operation was performed, the dura being found congested and bulging. This was incised and the temporosphenoidal lobe probed in various directions. Immediately following the operation, the Hiss extract was injected, and, although the case finally resulted fatally, the child lived for thirty-six hours with a temperature of over 107°, something, I think, quite remarkable, considering the condition. On the day following the second operation, lumbar puncture revealed the presence of a small extracellular diplococcus in the spinal fluid. This was one of those obscure cases in which a diagnosis could not be made until late, and considering the remarkable vitality of the child, an early use of the extract might have accomplished something, just as in the first case reported.

The other fatal case was also of this type. A man, thirty-seven years of age, was operated on for acute mastoiditis and the usual simple operation was done. Following operation the temperature did not come down, but continued to rise gradually, reaching 105°, and symptoms of meningitis gradually developed, accompanied by repeated chills. Secondary operation was resorted to and the sinus was found thrombosed and a well-marked meningitis, the dura of the middle fossa being injected and bulging. This was incised and a drain inserted in between the dura and brain tissue; the jugular was then excised. For the following two days the temperature fluctuated and gradually rose to 105°, pulse 154, and respirations 52. It was at this point, when the patient was taking the final change for the worse that the extract was injected, but it was of no avail and the patient succumbed in a couple of hours. This case is placed here because it was a suitable one for such treatment, but it is not a fair one to count against the extract, although in some of the other cases the condition seemed almost as hopeless. The other three cases, which were not suitable cases for this treatment, were the following: The first was a case of brain abscess, but the real cause of death was a very acute parenchymatous nephritis with uremia, a disease altogether outside of the sphere of useful treatment by a leucocyte extract. The second was a case of specific frontal sinusitis, on which multiple operations had been performed. Each of these cases received only one injection, when the nature of the lesion was recognized and treatment stopped. The third case was one in which the diagnosis was in doubt and was probably not an infection at all, but some intestinal disorder.

On the whole, therefore, I am more than satisfied as to the efficacy of the extract and am absolutely convinced that otherwise a fatal issue was inevitable in the above cases and that this was avoided by the extract. To get results in any disease, treatment must be started early, especially in such a disease as meningitis, where such a delicate mechanism as the nervous system is attacked. Once it gains a firm hold it is a hard matter to do anything.

A few words will not be out of place concerning the reliability of the opsonic index and its calculation. Lately some prominent authorities have reported that they found it unreliable in not agreeing with the clinical symptoms and also in that the calculations taken from the same cases at the same time by different observers have differed quite markedly from each other. Granted that these statements are true, and they assuredly are true in my experience, are they cogent reasons why we should condemn the opsonic index as unreliable and bring it into disfavor? Consider the practically parallel proceeding in making a blood count; does the result of the blood count always agree with the clinical symptoms? Do any two men get the same results when blood counts are made on the same case under identical conditions? You can all answer the first question; who among you has not had a case in which the clinical symptoms and the blood findings showed absolutely no correspondence, yet this fact did not induce you to condemn the blood count as utterly useless. You know that in the majority of cases it is reliable. The same is true about the opsonic index. Why then condemn this? The reason for failure in some cases, perhaps in the majority, is that it is mainly a question of the personal equation, that factor which we cannot get rid of. The results of a blood count lie practically in the hands of the one making it, and if he is conscientious and follows the technique, his results are to be depended on; but if he is not conscientious and looks upon this as an unwelcome piece of work,

to be done with as soon as possible, then it were better for you that you had done without this aid to making a diagnosis. The same applies to uranalysis or any laboratory work. That is one of the reasons why I make the plea that this opsonic work be left in the hands of those who are capable of doing it. The chances of error in the calculation of the opsonic index are far greater than those in doing a blood count, as the technique is more complicated and, unless the smallest details are worked out and the whole technique is rigidly adhered to, the results will vary. The reason why Wright and his immediate followers got such satisfactory results was because they were scrupulous in this regard. The results of such an authority as Hektoen in this country ought to carry some weight. In a series of acute infections, independent calculations were made by himself and four others under exactly the same conditions, and it was found that these calculations tallied, all showing the negative phase, and then the positive phase, and as the index rose the symptoms subsided. Hektoen further states that when properly and conscientiously performed it is quite reliable in the majority of cases and is, in fact, an indispensable aid. I have found it so in my experience.

I now come to the scientific side of the question and will briefly consider at the beginning some necessary facts that must be stated in order to understand what is to follow. The old ways of treating infections were tonic and supportive, obviously unsatisfactory, as they did not try to get at the cause of the disease. Now, by a study of nature's own methods of defence, as seen in infections artificially produced in animals, we endeavor to imitate her and to make use of the same weapons. This is the keystone of vaccine and serum therapy; it is around this pivot that everything revolves. In any disease we have two factors to consider: on the one hand the invading organisms; on the other the resisting forces of the body. Analyzing shortly the first, we find that all bacteria do not act on the body in the same way, that in fact their methods of attack differ widely from each other. They all have a common action in the sense that they act mechanically, just like any other foreign body introduced into the body; that is, they act by their physical presence. This is a comparatively unimportant point, its only importance practically lying in the fact that it may lead to embolism in the vessels. The vital ways in which the bacteria act may be divided practically into two classes: in the first class we have those bacteria which secrete soluble, diffusible bodies in the media in which they thrive, called toxins. These toxins are readily given up to the circulating fluids of the body, and it is through the agency of these toxins that the bacteria produce their baneful effects on the body. The second class, and this is the important one for us to consider, as to it belong the organisms which we have been considering above, comprises that class which elaborate within their own bodies, a class of substances known as endotoxins. These endotoxins are retained within the bacteria elaborating them, not being given up to the culture media or the circulating fluids, but only being set free when the bacteria are dead or dying. It is probable that some species of bacteria act in both ways, by a soluble toxin and by an endotoxin. To this class the tubercle bacillus probably belongs, the active toxin being an endotoxin and the soluble one being an accessory one. It was to combat this latter, the soluble one, that Koch introduced his old tuberculin, and since the real toxin is thought to be the endotoxin, the reasons for failure of the old tuberculin are apparent.

On the other hand, we have to consider Nature's ways of fighting these bacteria. When a foreign substance is introduced into the body, especially if that foreign substance is of an albuminous nature, the system, by the very presence of this material, is stimulated to the formation of what are known as antibodies, that is, bodies whose function it is to neutralize the effects of or destroy the substance introduced. Obviously, these antibodies must be of many different varieties, depending on the character of the antigen, calling for their formation. Applying this principle to the bacteria forming the soluble toxin, we will have the formation of an antitoxin. The examples of this class are perhaps the most familiar to us, diphtheria antitoxin and tetanus antitoxin being of this nature. Against the second class we would have the formation of bactericidal and bacteriolytic bodies, which would destroy and dissolve the bacteria, setting free the contained endotoxin. It is important to emphasize at this point that when the bacteria are destroyed and dissolved by the foregoing serums, the endotoxin is not necessarily neutralized; in fact, is not generally so. This point will again come up in the discussion of these serums. Lastly, under the heading of defence, we must consider an important factor—the phagocytes themselves. The question of the origin of the antibodies whether they are derived from the phagocytes, as Metchnikoff holds, or from other sources, as other well-known investigators claim, is entirely outside the scope of this short paper, but whatever view we hold, we must all admit the great importance of the phagocytes themselves. Since the action of the opsonins is intimately bound up with that of the phagocytes, these will also be classed here. It may be well to define exactly what opsinins are. The name is from the Greek and freely translated means, "to prepare, for eating" or "I prepare for eating." The opsonins are normally present in the blood serum, and, as the name implies, they act on the bacteria in some way, preparing them for ingestion by the phagocytes, that is, they prepare them, so that the phagocytes can the more easily eat and digest them. Hence, indirectly, they act by stimulating the phagocytes and hence the placing of these two factors together.

Based on the preceding ways, in which nature copes with infection, we have four classes of therapeutic agents, each one differing from the other in the fundamental, underlying principles of application. These four comprise the antitoxins, vaccines, bactericidal and bacteriolytic serums, and the leucocyte extracts. It is not necessary to deal with the antitoxins, as their use is well known. The second class, the vaccines, are one of the important subdivisions to be dealt with at some length. By the use of vaccines, either attenuated cultures of the living bacteria or, as is now more often the case, killed cultures, we aim to stimulate the body to increase its formation of antibodies and thus to overcome the infection. The point to be emphasized here is that the body itself must form its own antibodies, that is, an active immunity must be brought about. The significance and great importance of this statement lies in the fact that it takes some time for this immunity to be developed; it is

not a matter of hours or of a day, but several days, generally three or four at least, and sometimes much longer. During this period, in which the antibodies are being formed and consequently immunity is being developed, it is a well-established fact that the resisting powers of the body are not only not increased, but are actually diminished in the large majority of cases. This is the so-called negative phase and is a very important factor to be remembered. This phase can easily be shown on the chart of an opsonic curve, where, following an injection, we have a decided fall in the curve and after a varying period, depending on the dose and other factors, a rise to a point higher than the previous reading. A practical everyday example, probably not an exactly parallel one, is the Widal reaction in typhoid fever. Here we do not get the agglutinating action of the serum, the evidence of antibody formation, for several days after the clinical symptoms of the fever have appeared; when reaction has well set in, we get it. I will illustrate this point further by reverting to the case of intestinal tuberculosis which ended fatally. This patient had a temperature of about 101° F. and all the symptoms of a systemic intoxication were present.

This case was decidedly not a suitable case for such treatment. Take, for example, a systemic acute infection, such as a case of acute septicemia, in which we have high temperature and all the symptoms of a grave constitutional intoxication. If it were put to a vote of clinicians, as to whether they would use a vaccine in such a case, I have no doubt whatever but that many might favor such a course, and yet nothing is more illogical and nothing could be more harmful. Consider the state of affairs present in just such a case; interpret the symptoms. The train of symptoms or the bacteremia is simply the way the body has of showing that it is being hard pressed and as the symptoms increase in severity the lines of defence are being broken down; that it is being defeated in the struggle, that its poor, worn out, jaded cells have exhausted their powers of antibody formation. How unfortunate then to use a vaccine in such a case, calling upon the cells to form more antibodies, when they are already exhausted. Following this injection, for several days we find the body more open to infection, it being in the condition, spoken of above, as the negative phase. Yet this is being done every day, especially in the treatment of tuberculous patients, simply by the clinician not knowing or not realizing the nonsuitability of the case for this treatment. It is an absolutely different consideration, when the case is subacute or chronic. Here a rational and closely watched course of treatment with the vaccine is of almost specific value in some cases. The above considerations apply to constitutionally acute cases, in contradistinction to the locally acute cases, as these latter were the classes of cases that were markedly benefited.

The next point in a consideration of vaccines is the kind of vaccine to be used, that is whether autogenous, that cultivated from the patient, or a stock vaccine. To my mind there are no two sides to this question as in all cases it should be an autogenous vaccine, although I have used the stock one in some few cases. The vaccine, as explained above, stimulates the formation of antibodies and opsonins and so far experience seems to show that these antibodies and opsonins are specific, that is, that a certain bacterium will give rise to a certain antibody or a certain opsonin and that anti body or opsonin will be effectual against that bacterium and against that alone. It is easy to see then why we should use an autogenous vaccine. The stock vaccines are made up of mixtures of different strains of bacteria of the same or allied species. If a strain of the particular offending organism is present, we may get results, but if it is not present, then the specific antibody or the opsonin is not stimulated to formation, and no good results from its use. The system, with a stock vaccine, is called upon to form a whole series of antibodies, corresponding to the varieties introduced, and these have no function to fulfill, as there are no corresponding bacteria to oppose, so that the energy of the system is spent in useless work. The energy is not a trifling force, to be thus dissipated. This observation applies to all stock vaccines, but especially to vaccines of bacteria, such as the staphylococcus and the streptococcus. When we consider the multiplicity of forms of such bacteria, it is easy to see why stock vaccines fail in some cases, in which the results with autogenous vaccines have been so brilliant. We are all familiar with the many varieties of streptococcus, differing as they do so little in morphology and straining properties and, what is most important, so much in their pathogenic action. In some work, in which I am now engaged, at classifying the various bacteria found in the tonsils, one is at once impressed by the many varieties of streptococcus isolated. When we consider the staphylococcus, the same holds true; we see differences in pathogenicity, pigment formation, liquefaction of gelatin and their cultural characteristics in general. These are but examples; the list is almost endless. Thus we can understand that in a given case unless the invading organism forms one of the strains in a stock vaccine, probably no effect is produced. Again, why do we need stock vaccines at all? Needless to say, the microbial cause of a disease must be known before a rational attempt can be made to treat with a vaccine. If we can get enough of the discharge to make a bacteriological examination, we can at the same time make cultures and prepare a vaccine. In the above series of cases, a stock vaccine was used in treating some of the cases of tubercle infection, on account of the difficulty of preparing this vaccine, but just as soon as possible, an autogenous vaccine was substituted; also, in one case of tubercular adenitis, which did not improve under the human tuberculin, bovine tuberculin was substituted and this was of necessity nonautogenous. The gonococcus is rather hard to prepare as a vaccine on account of the fastidiousness of this bacterium, which grows only on special media and quickly dies out. As there are probably few varieties of this bacterium, the results with the stock vaccine have been rather good, but in all cases it is better to use the autogenous one. The stock ones may not be fresh, and this is quite an important point, as, even with autogenous ones, it is better to make new vaccines every few weeks.

The third class of agents comprise the bactericidal and bacteriolytic serums. For the production of these, just as in the formation or preparation of antitoxin, we immunize animals, such as the horse, against the pathogenic organism, and the serum of such animals is then used for injection into patients suffering from infection with that organism; in other words, we get the cells of the animal to manufacture the anti-bodies and then use these bodies ready made, so to speak, for injection into

patients. Thus, in this class, it is a passive acquired immunity that is brought about, the cells of the patient taking no part in the process. This would be an ideal condition of affairs, supplying the body with its weapons ready for use, but unfortunately the practical results have not been encouraging. Mainly for this reason, and also because the theoretical considerations are, on the whole, opposed to such serums, I have not used them. One point, and this seems to be more than theoretically established, is the fact that a bactericidal serum is not necessarily, and in fact is not generally, antiendotoxic; that is, that, although the bacteria are killed, the contained endotoxin is not neutralized but is actually set free as a poisonous body having free rein to act injuriously on the body. Therefore, when an injection of such a serum is given, so much endotoxin may be set free that the body succumbs to the severity of the infection. The question of anaphylaxis also comes into question here. The actions of such serums may be utilized either as prophylactics or as curative agents. The first does not interest us practically, as most of our cases are well advanced when we are called to treat them, and hence are not subjects for prophylactic measures, and as curative agents they have proven failures. Lately the so-called polyvalent serum against streptococcus infections is being again brought into use. This is made by immunizing suitable animals against a number of strains of streptococcus and using the serum of such animals in man. Now, in the immunity developed after a streptococcus infection, the serum does not possess any marked bactericidal or antitoxic properties, but rather acts by stimulating phagocytosis or more probably by supplying opsonins. It is hard then to see why such a serum, as the streptococcus serum, should act as a bactericidal one. Many have claimed that it has not only protective properties but also curative ones. It probably has some action in supplying opsonins, but it is open to all the objections cited against bactericidal serums in general, and in addition lacks one very necessary quality—that of specificity, it really being on the order of the old gunshot prescription—empiricism as opposed to rationalism.

The next subdivision deals with the leucocyte extracts and the rationale of the Hiss extract is based on the all-importance of the leucocytes in the struggle against infection. If we consider the phenomena presented to us in inflammation, we are at once impressed by the important rôle which leucocytes assume and their importance in the fight waged against the invading army. Soon after the infection is set up, we have a vast army of leucocytes or, as they are now better known, phagocytes, hurrying to the point of attack and actively combating the bacteria. This is true of the infections in general, and especially so in the infections which we are ordinarily called upon to treat. In the struggle that ensues many of the phagocytes are killed, others are maimed or injured, and all are more or less worn out. If the bacteria are the stronger the body is overwhelmed; if the phagocytes, the infection is overcome and the body returns to the normal. All the different leucocytes are not equally important, the main ones concerned in the majority of infections being the polynuclear neutrophiles and the large mononuclear leucocytes. It follows then logically from the above that if we can assist or strengthen the leucocytes in any way, we will at the same time enhance the chances of the body overcoming the infection. Hiss divides the protecting factors involved into two classes; in the first he places the antibodies, such as the agglutinins, lysins, opsonins, etc. These are readily produced by the cells and given up to the circulating fluids of the body. In the second class he places the endobodies of the leucocytes. He assumes that these endobodies are present in the bodies of the leucocytes elaborating them and are not as a rule given up to the circulating fluids, as the first set were, but are retained in the bodies of the phagocytes, manufacturing them, serving to protect them and in this indirect way also protecting the more highly specialized cells. Therefore, if we furnish to the phagocytes the bodies of which they are deprived in the fight, that is, furnish them quickly and directly with their weapons of warfare, they would be the better protected from destruction and would be in better condition to carry on their work of ingesting the bacteria and would the better be able to recuperate quickly. With this end in view Hiss proceeded to make an extract of rabbit's leucocytes, hoping that it would contain the above bodies and that by the injection of this extract into patients, the victims of infections, the phagocytes would thus be strengthened. For several reasons preference was given to extracts rather than to the intact leucocytes as the former are the more diffusible and would thus be carried very quickly to the affected parts, protecting not only the leucocytes but also the more highly specialized cells. Also, bearing in mind the probable specificity of opsonins, the intact leucocytes of a foreign animal, such as the rabbit, may not find in the serum of man the necessary opsonins for their stimulation and activation, or the opsonins may be depleted by the disease. Moreover, experiments were carried out with such leucocytes with practically no results. An extract is independent of these considerations. The results of experiments in animals, and of treatment of infections in man, has apparently borne out the truth of this assumption. Analyzing the results, it would seem that this extract does not act through any bactericidal, bacteriolytic, or phagocytosis-stimulating power, but that its very marked favorable influence on the temperature and especially on the general condition, is in all probability referable to its neutralization of the toxic products; that is, ordinarily speaking, to its action in combating the condition which we describe as sepsis or toxemia.

Such being the principles on which it acts, we can see the advantages of such an extract. In the first place, we inject only substances which are normally present in the body; the reaction, therefore, following the injection is practically negligible, only a very slight reaction being present in some cases and these are few. Secondly, the body is not called upon to expend any of its energy in the developing of an immunity, that is to form antibodies. This is an important factor, as was shown in the discussion of vaccines. Another factor, and this is probably the most important one, is that the effects of the extract are immediately felt, within a few minutes after injection, or at most within a few hours. The advantage of this in an acute case is apparent. Although given in doses of 10 c.c. it is very quickly absorbed. There are some few disadvantages. We have no methods of standardizing, and of necessity, therefore, the extracts, made at different times and from different animals, must vary. This objection does not amount to anything practically, as the bodies in the extract are normally present in the

body and an increase does not do any harm, the excess being all to the good. Again we are at sea regarding the length of time of its action and also the proper dose. These also are not important practically, as we can guard our injections by the clinical symptoms. Some of the other great advantages are that we do not have to isolate the offending organism, as the action of this extract is absolutely independent of the bacteria, depending only on the resisting powers of the body. The great importance of this statement will be appreciated when the treatment of some of those obscure cases of sepsis come up, in which the causal factor cannot be isolated, but which are surely due to some invading organism, or in cases of mixed infection, when we are in doubt as to the primary organism, as in the meningitis case reported.

Incidentally, I might here mention that Dr. Adrian Lambert reported recently a series of cases which interest us, as we occasionally have to deal with erysipelas complicating mastoid, and other operations. He reports fifty-one cases of erysipelas of all kinds, treated on his service at Bellevue Hospital with the Hiss extract. In cases so treated within forty-eight hours of the onset the extract acts almost like a specific, the temperature dropping almost to normal, the attack being thus cut short. In all cases the symptoms were much alleviated, temperature lowered, nausea and vomiting stopped, and the complications and sequelæ were of much less frequency. In cases treated late, the succeeding septicemia was in many cases aborted. Some interesting statistics are furnished in cases of erysipelas in infants under one year of age. Before the use of the serum his mortality rate was 100 per cent. Out of six cases treated with the extract four survived, or over 66 per cent., a great difference surely.

Briefly recapitulated, then, the conclusions to be deduced from my own work are as follows:

1. In acute constitutional diseases, such as pyemia, septicemia, and sapremia, the vaccines are contraindicated. In such cases the leucocyte extract finds its greatest field of usefulness and will often save cases which are apparently hopeless. Some authorities do use vaccines in such cases, with the admonition to avoid the negative phase by proper dosage and very guarded administration. This sounds easy, but it is an entirely different matter to apply in such a case. Therefore use the extract of leucocytes in such cases, and avoid vaccines calling for active immunization.

2. In the locally acute (without systemic symptoms), subacute, and chronic cases, the vaccines find their greatest field of usefulness and will be found to act almost as specifics. I have had no experience with the leucocyte extracts in such cases, but they should be effective, especially in the subacute and the locally acute, and certain types of chronic cases in which the diseased focus is not walled off by a firm, hard fibrous wall. However, the results have been so good with the vaccines that I have not felt the necessity of using any other agent.

3. In all cases use autogenous vaccines in preference to stock ones, as the results will be better and surer and the administrator knows exactly what he is adminstering.

4. Make fresh vaccines frequently, so as to ensure their greatest potency.

5. Be guided in the administration by the clinical symptoms, but at the same time do not neglect to calculate the opsonic index. In the majority of cases it is just as reliable as a blood count is.

6. Do not use tuberculin in tuberculosis when general constitutional symptoms are present, that is, when the patient is in the pyrexial stage. First, localize the process as much as possible and then start the treatment, interrupting it if the condition again becomes general.

7. Give small doses often repeated, rather than large doses seldom repeated. In all cases start in with a minimal dose and then increase it.

8. Always have in view, even in the simplest case, the danger of anaphylaxis or hypersensitization. This is no negligible quantity.

9. Always combine with the vaccine treatment the other general medicinal and hygienic measures. This vaccine therapy is not a cure-all.

10. If you have a case of septicemia, such as that which follows sinus thrombosis, and your surgical measures have been exhausted, do not wait until the patient is *in extremis* or moribund, but start the use of the extract early, so as to give your patient the best chance. The extract is not a miracle worker. Most of the cases of the series reported to-night were very far gone and were really in the final stage. A more severe test of the efficacy of an agent could not have been devised.

Serum and vaccine therapy do not comprise agents which can be doled out by a certain dose, such as a general medicine, but it absolutely demands, for its intelligent administration, a certain degree of knowledge and skill which cannot be acquired outside of a laboratory. Also out of justice to the patient, who in good faith trusts himself for treatment in our hands, fair play demands that we should do our best by him. Hence the average man, unskilled in this way, should recognize his limitations and avoid the possibility of doing harm and of bringing such an important therapeutic measure into disrepute. On the other hand, these agents should be given a fair trial and should no longer be neglected, as they have been in the past, by the specialist.

In conclusion, I wish to state that the major part of this work was carried on in the laboratory of the Manhattan Eye, Ear, and Throat Hospital, New York City, and in this connection I wish to express my appreciation of the many kidnesses of Dr. Jonathan Wright, the director of the laboratory and instigator of this line of investigation; of Dr. E. G. Zabriskie, the pathologist; and of Mr. S. Richardson, the laboratory assistant. I also wish to extend my thanks to the surgeons and the assistant-surgeons of the above institution, who gave me the opportunities of treating their patients. My sincere thanks are also due to Drs. W. T. Connell and William Gibson of Queen's Medical College, Kingston, Canada, my Alma Mater, who instructed me in the technical methods of vaccine preparation and the latter of whom placed his case records at my disposal for reference. Dr. J. H. Güntzer was a coworker with me on the cases of rhinoscleroma and my thanks are also due to him. To Dr. Philip Hanson Hiss, Jr., Professor of Bacteriology in the College of Physicians and Surgeons, Columbia University, New York City, my sincere thanks are hereby extended for his uniform kindness and courtesy to me during the investigation and treatment of the series of cases with his leucocyte extract. Lastly, I wish to express my appreciation of the kindness of my associate, Dr. William Henry Haskin, whose sympathy and encouragement provided a constant stimulus to me in the prosecution and the continuance of this work.

11 East Forty-eighth Street.

A SIMPLE COMPLEMENT FIXATION TECHNIQUE IN SYPHILIS.

REPORT OF CASES.

By ALEXANDER FLEMING, M.B., B.S. LOND., F.R.C.S.,

AND

FRANK J. CLEMENGER, M.D.

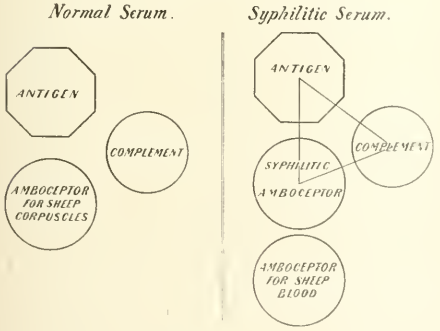
ASHEVILLE, N. C.

ASSISTANTS IN THE DEPARTMENT OF THERAPEUTIC IMMUNIZATION, ST. MARY'S HOSPITAL, LONDON, ENG.

If one animal is injected with the red corpuscles of another it will develope the power of hemolysing the red corpuscles of the species to which the second animal belonged; that is, if some of the serum of the first animal is mixed with the red corpuscles of the second they will become laked. This solution of the red corpuscles was shown by Bordet to be due to the action of substances similar to those that had already been described in connection with the lysis of bacteria by immune sera, and they are best known as amboceptor and complement. These two substances act in conjunction, but neither is capable of causing hemolysis by itself. They vary widely in their properties, for, whereas the complement is present in the serum of all animals, both immunized and unimmunized, the amboceptor is present only in those animals which have been immunized. The complement is easily destroyed by heat and when kept under artificial conditions, while the amboceptor is comparatively resistant to both. Again, an animal which becomes infected with a microorganism will react to the infection, by the production of specific antibodies, in the same manner as an unimmunized animal. These specific antibodies are not found in animals which have not been infected, or immunized, so that if we are able to demonstrate the presence of such antibodies in the serum of animals we then have evidence of infection.

The serum of some species of animal shows, however, a hemolytic power for the red corpuscles of certain other species, and this is easily demonstrated when human serum is mixed with the red corpuscles of the sheep. This lytic action is due to the same combination of substances which brings about the

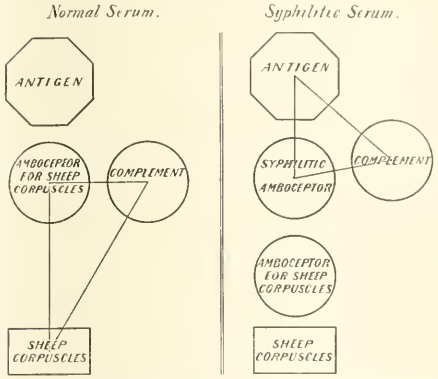
DIAGRAM No.I.



lytic action of immune sera. Thus, we have seen that a solution of the red corpuscles of one animal, when mixed with the serum on another, may be due (1) to the fact that the second animal has been immunized by the injection of the red corpuscles of the first, or (2) that the first animal possesses a natural hemolytic power against the red corpuscles of the second.

Wassermann's original application of the Bordet-Gengou complement fixation test to syphilis made use of the first of these two alternatives and used the hemolytic amboceptor derived from the serum

DIAGRAM No.II.



of a rabbit which had been immunized against sheep corpuscles, while for complement he used that found in the serum of a guinea-pig. This method is still largely used for the diagnosis of syphilis, as a serum method, but it is quite complicated and to do away with some of complications, especially that of immunizing a rabbit to sheep corpuscles, Bauer applied the second of the two alternatives given above and made use of the hemolytic amboceptor for sheep corpuscles which is naturally present in the serum of human beings.

A further simplification of Wassermann's technique was made by utilizing the complement which also exists in the serum naturally. This modification by Hecht did away with the guinea-pig complement. While these modifications were being made the preliminary steps were also being modified, so that it was soon demonstrated that other extracts, besides those made from the organs of a syphilitic fetus, would serve, and that alcoholic extracts were quite as efficient as saline ones. Less complex chemical substances were also tried but with less satisfaction.

Thus, in Hecht's method, all that is required beside the serum to be tested are a suitable tissue extract and some washed sheep corpuscles, but as Hecht performed the reaction a considerable quantity of serum was required. This necessity was overcome in a technique devised by one of us (Fleming) whereby the test can be carried out using only about twenty cubic millimeters of serum. The method is the same as Hecht's, but the details of the technique are different, and are as follows:

Substances required, (*a*) Alcoholic extract of heart muscle; (*b*) Serum to be tested with normal and syphilitic controls; (*c*) Washed sheep corpuscles.

The heart extract is made by grinding up in a mortar several grams of heart tissue, adding five cubic centimeters of 90 per cent. alcohol for each gram of heart muscle used. The mixture is then heated, at 60°C., for one hour, and after standing at room temperature for twenty-four hours is then ready for standarization. This is done by diluting

the extract with 1 per cent. salt, in strengths of 2.5, 5, 7.5, 10, and 15 per cent., and using each of these dilutions with several syphilitic and non-syphilitic sera in a manner shortly to be described. The strength which is best to use, as determined by this standardization, is that which will give complete deviation of the complement, in the syphilitic sera, without interfering with the hemolytic power of normal serum. It will probably be found that this strength is somewhere between 5 and 10 per cent. The extract usually keeps well for several months, after being standardized in the beginning, and no further trouble need be taken in this direction, as the controls which are used in the actual testing are sufficient to determine its value. After several months the extract will lose its power of deviating the complement in all syphilitic sera, and when one uses a stale extract a certain number of diagnoses may be missed though the patients are undoubtedly suffering from syphilis. The results one obtains by this method are entirely dependent on the efficiency of the extract.

The serum of the patient and controls is best taken in a capsule, such as is used by Sir Almroth Wright in collecting blood for determination of opsonic indices, and one capsule will usually furnish sufficient serum to repeat the test, should it be necessary. The blood is taken from the finger, and it is better to use the serum while fresh, but this is not always essential, as the hemolytic power of human serum for sheep corpuscles does not deteriorate for several days; we have used serum ten days old with satisfactory results. Should it be found, however, that a satisfactory result is not obtained with old serum it will probably be found that the complement has deteriorated, in which case it will only be necessary to repeat the reaction, adding fresh complement, in the form of guinea-pig serum, or fresh human non-syphilitic serum. If guinea-pig serum is used it can be readily obtained by passing a suitable needle into the ventricle of the guinea-pig and the serum is readily separated by centrifuging. We have taken as much as five cubic centimeters from a guinea-pig without apparent injury.

The sheep corpuscles are obtained from the butcher, who either whips the blood, or takes the blood into a bottle containing a 1.5 per cent. solution of sodium citrate. The citrate, or serum, is washed out by centrifuging with 1 per cent. salt solution, several times, and the corpuscles are used in a 10 per cent. strength made up with 1 per cent. salt. The better plan is to use the citrate solution which prevents the gross contamination which takes place when the butcher whips the blood.

To standardize the extract, and also for the purpose of doing the actual test, one uses, in the place of ordinary test tubes, small tubes of similar shape which are made by drawing out in the blow-flame pieces of glass tubing (about 5 millimeters diam.) one inch long, which are sealed at both ends. These are then notched with a file and when broken make a pair of miniature test tubes. These tubes are put up in two rows, of five tubes each, and into the first tube of each row is put four volumes (each volume representing 10 cubic millimeters, but exact standard is immaterial) of a 2.5 per cent. solution of the extract in 1 per cent. salt. Into the next tube of each row is put four volumes of a 5 per cent. solution of the extract, and so on, with the strengths of 7.5, 10, and 15 per cent. Into each tube of one row is now put one volume of a syphilitic serum, and into each of the tubes of the other row is put one volume of normal serum. The contents of the tubes are now thoroughly mixed by inverting several times, and they are incubated at 37°C, for one hour. At the end of this time they are taken out of the incubator and to each tube is added one volume of the 10 per cent. suspension of sheep corpuscles, after which they are then incubated for another hour. It will then be seen that in the case of the syphilitic serum, in all, except, perhaps, the lowest one, or possibly two dilutions, there will be no hemolysis owing to the fixation of the complement by the extract and the specific amboceptor, while in the case of the normal serum there will be hemolysis in all the tubes except perhaps that containing the strongest dilution. The strength which should be chosen, as determined by this test, is the strongest which will completely inhibit hemolysis with the syphilitic serum without interfering with the hemolytic power of the normal serum.

In doing the actual test one takes the same miniature test tubes and makes the following mixtures:

First pair. (1) Extract, 4, normal serum, 1; (2) Salt solution, 4, normal serum, 1.

Second pair, (3) Extract, 4; syphilitic serum, 1; (4) Salt solution, 4, syphilitic serum, 1.

Third pair, (5) Extract, 4; patient's serum, 1; (6) Salt solution, 4, patient's serum, 1.

And so on for each patient, one tube containing four volumes of the extract with one volume of the patient's serum, and one tube containing four volumes of salt solution with one volume of the patient's serum. The tubes are now incubated for one hour, after which the sheep corpuscles are added and they are then incubated for another hour. The results will show: Hemolysis in tubes 1, 2, 4, and 6 if the patient is syphilitic, while tubes 3 and 5 will show no hemolysis because of the complement fixation.

Diagram No. 1 will illustrate graphically what takes place in the tubes during the first hours' incubation. Both the normal and syphilitic sera contain complement and hemolytic amboceptor, but the syphilitic sera contains, in addition, a syphilitic amboceptor. This last amboceptor incubated with the heart extract binds itself, and the complement, to the extract while in the normal serum there is nothing to bind the complement to the extract, so no change takes place. In tubes 2, 4, and 6, where salt solution takes the place of the extract, the complement is left free, the salt solution having no binding power between amboceptor and complement.

The second diagram illustrates what takes place during the second hour's incubation. In the mixture with the syphilitic serum and the extract, the complement having already been bound up to the extract, is no longer available to act with the hemolytic amboceptor and cause hemolysis of the sheep corpuscles which have been added, so no further change occurs. With the normal serum and extract there was no change during the first hour's incubation, so the complement and the hemolytic amboceptor are both free to unite with the sheep corpuscles producing hemolysis. The same can be said of all the tubes containing salt solution, whether the serum is normal or syphilitic.

In a certain percentage of cases there is an absence of hemolytic power (about 5 per cent. of all cases tested) for sheep corpuscles. This may be due to a want of complement or hemolytic amboceptor. It is only discovered when, on completion

of the second incubation period, one sees no hemolysis in the tube containing salt solution, serum, and corpuscles. If the failure is due to lack of amboceptor then one simply adds to both tubes of this particular serum one-half volume (5 c.mm.) of one's own serum, which has been previously heated for one-half hour to 56°C, and which has been proven to have hemolytic power. The heating will have destroyed the complement of the serum added, but the hemolytic amboceptor will be left unaltered, and this, in combination with the complement of the patient's serum, will cause hemolysis in the tube containing salt solution, serum and sheep corpuscles, and will, or will not, cause hemolysis in the tube containing the heart extract, accordingly as the patient has, or has not, syphilis.

However, if it is the complement that is wanting in the serum, the easiest way to overcome the difficulty is to repeat the test and add, in addition to the one volume of the patient's serum, a normal hemolytic dose of one's own serum. The tubes are incubated for another hour if the amboceptor was deficient, but if the test is being repeated from the beginning with the addition of the complement, the routine of the actual test is carried out. By using the one or the other of these modifications it is possible to obtain trustworthy results in every case.

The results we have obtained with this simple method have been extremely good. The following is a detailed list of our cases:

	POSITIVE.	NEGATIVE.	DOUBTFUL.
Syphilis with active lesions:			
Primary	13	1	0
Secondary	50	0	0
Tertiary	161	2	7
Congenital	38	0	0
Syphilitic history without lesions	38	19	2
General paralysis	31	1	3
Tabes	6	3	2
Supposed non-syphilitics	22	745	4

In the primary cases thirteen were positive and only one negative. The earliest case tested was fourteen days after the appearance of the primary lesion and this gave a positive result. The case appearing as negative was one having an initial lesion three weeks old.

All the cases showing secondary lesions gave positive reactions. Of the tertiary cases showing definite lesions, 161 were positive, while 2 were negative and 7 doubtful. The congenital cases gave positive results and can be divided into two broad classes: (*a*) Cases of infants with syphilitic eruptions; (*b*) Older children with ocular troubles, *i.e.* interstitial keratitis, choroidoretinitis, etc., the results being quite definite in both groups.

In connection with the congenital cases it is interesting to note the reactions of some of the mothers. In most cases the mothers gave a decidedly positive reaction, but in two instances the reaction was not convincing.

Thirty-eight cases were tested in which there was a definite history of syphilis, but which presented at the time of examination no lesions. Some of these cases had had mercurial treatment for two or three years, and the supposition was that they were cured, while others had only had treatment irregularly.

Of the hospital cases having a history, by far the greater number gave a positive reaction, regardless of the length of time elapsing since infection, and this is probably due to the fact that the hospital class of patients treat the infection with too little seriousness, and is apt to neglect the treatment after the active lesions have disappeared for a little time. Quite a different state of affairs is seen in the better class of patients where the treatment is persisted in religiously for several years. Here most of the reactions, in patients having finished treatment, are negative, although in some cases where there is no doubt that the prescribed course of treatment was thoroughly carried out, positive reactions may be obtained.

The following case is of interest in this connection. Patient, a medical man, contracted syphilis in the course of his medical duties. He was treated for four years with mercury by mouth. Treatment had ceased for two years, when on testing his blood, repeatedly, it invariably gave a positive result. He recommenced treatment of the strength of the reaction, although he had had no lesion since treatment had been stopped. His blood was tested almost daily during his new course of treatment, and 100 grams of soamin, intramuscularly, in graduated doses did not change it. This was followed by mercury pills with the same result until the dose had been increased to the point of mercurial poisoning. Two weeks after this he gave a negative serum reaction. This was over six months ago and the reaction has remained negative ever since.

In another case the reaction was taken after the case had been treated for fourteen months, and it gave a positive reaction. This was repeated several times in the next month, always with the same result. No tests were done with this blood for the next three months, but after this interval he was again tested and found to be negative, which reaction still persists. It is interesting to note that during the interval between the first and second series of tests the patient continued to take mercury in exactly the same dose.

In connection with the parasyphilitic infections, the general paralytics give excellent results, but the tabetics are the least satisfactory of all conditions supposed to be the result of syphilitic infection. Our list includes 35 general paralytics, of which 31 were definitely positive, 3 doubtful, and 1 negative. This one, which was recorded as negative, was subsequently tested and found to give a positive reaction, so that in all probability the first result recorded was due to unnoticed error. In addition to these there was one other case which was clinically general paralysis, but which gave a negative reaction, and on examination of the spinal fluid, by an independent observer, there was no increase in the lymphocytes.

Few tabetics have been tested, but of the eleven tested five were positive, two doubtful, and three were negative. Of the three negative cases one had certainly had syphilis, but the other two strenuously denied having had an infection.

As regards the control cases, in which there was no suspicion of the existence of syphilis, we have tested 771 cases, some of these being healthy persons and some others being patients attending the hospital for other diseases. Of these twenty-two gave positive reactions, while four were doubtful, these four being cases in which there was a deficiency in the hemolytic power of the serum, and which were done early in the research before we had had much experience in combatting this deficiency.

The twenty positive cases included were two cases of leprosy and several cases of gonorrheal infection, and on close inquiry into the history of these patients there seemed some grounds for believing

that in every case, with the exception of one of the cases of leprosy, in all probability, there had been a syphilitic infection.

From a consideration of the figures given above it would appear that this simple method used gives as good results in the serum diagnosis of syphilis as any of the more complicated procedures.

The objections which can be raised to it are, first, that in a certain percentage of cases there is no hemolytic power for sheep corpuscles, in the serum to be tested, and, secondly, the reaction may fail in cases where there is only a small amount of antibody and much complement in the serum. As regards the first objection, we have shown above how it can be met without using any but the most simple procedures, and our actual results clearly show that the second objection is purely a theoretical one, and one which need not be taken into account in practice. The method requiring as it does only the preparation of a suitable alcoholic heart extract (which can be kept in stock) and the obtaining of sheep's blood is, we think, the least complicated method which has been devised for the purpose, and the easiest to perform in the hands of other than trained laboratory men. Emphasis must be placed on the fact, as stated in a previous communication by one of us, Clemenger, however, that the results are dependent entirely on the efficiency of the extract.

IN WHAT WAY CAN LARYNGOLOGY AID IN MAKING THE DIAGNOSIS OF INCIPIENT PULMONARY TUBERCULOSIS.*

By WOLFF FREUDENTHAL, M.D.,

NEW YORK.

If the question were asked what are the symptoms in the upper air tract from which a diagnosis of incipient pulmonary tuberculosis can be made, it would be impossible to give a mathematically correct answer. It will be my aim, however, to attempt to outline certain symptoms which are partly pathognomonic of the disease.

For many years the writer has made systematic examinations of all patients admitted to the sanatorium for consumptives at Bedford Station. Many of them were suffering from incipient tuberculosis of the lungs, while in others the diagnosis was not at all positive. By following this plan a picture of the entire upper air tract was gained, which, in connection with other symptoms, enabled us to state that in certain cases there was in all probability a tuberculous lesion of the lung present, in others not.

Beginning with examination of the condition of the nose, it must be confessed that the symptoms here are not at all significant. A recent writer who examined 156 cases of pulmonary tuberculosis found that 150 of them were suffering from a deviation of the septum. While such deviations are certainly present, the above number is surely an exaggeration. The same writer found about as many hypertrophies in the nasal chambers. *A priori* one would not expect hypertrophic conditions in a wasting disease like phthisis, and statistics gathered by the writer† and others show just the contrary. Indeed, we frequently find atrophic and dry conditions in the nose, but in the individual case we cannot identify them with any tuberculous lesion.

Of greater importance is the examination of the posterior pharynx, especially the vault. I will not mention adenoid vegetations here; they seem to me to be but the reaction of the organism against the invasion of the tubercle bacillus. These growths have been examined by the hundreds, but comparatively seldom has the tubercle bacillus or tuberculous tissues been found in them.

What we do frequently find at the vault of the pharynx are bleeding vessels. The writer years ago called attention to this point, as well as to ulcerations occurring on the same spot. If you examine a large number of cases carefully, you occasionally meet ulcers, though they are not so frequent as hemorrhages. In fact, the latter are so significant of a tuberculous invasion that we may almost call them pathognomonic, as spontaneous hemorrhages do not occur in any other disease. Only once has the writer had occasion to plug the posterior nares for bleeding from the vault of the pharynx, and that was in a case of purpura hæmorrhagica. The syphilitic lesions in that neighborhood are of an entirely different character.

More remarkable, however, is the extreme pallor and anemia of the mucosa observed all along the hard palate and including the mucosa of the soft palate back to a certain line. This extreme anemia is the more striking by contrast with the marked congestion further down. This line of congestion begins at the point of insertion of the uvula, and extends down on both sides over the arches, including the tonsil and its vicinity.

Another symptom to which the writer has drawn attention are the hypertrophies of the lymphoid tissue at the base of the tongue. These hypertrophies of the lingual tonsil have been observed in perhaps 50 or 60 per cent. of all tuberculous cases, and seem to be directly contradictory to what has been said above regarding hypertrophies in general; but I believe that this part of Waldeyer's ring is in the same relation to the tuberculous process as adenoid growths. They become enlarged, perhaps, for the same reason—that is, as the result of a reaction of the organism against the invasion of the tubercle bacillus. Here at the base of the tongue we might well consider the probability of ingestion tuberculosis; the food passing over this area is more apt to adhere to it than farther up. However, this is only a theoretical deduction. Enlarged veins at the base of the tongue are not often encountered, and bleeding from this region, as is quite common in other affections, is almost unknown in tuberculosis.

Again, the epiglottis, or rather, the tip of the epiglottis, which in the incipient stage is generally very thin, shows marked anemia, while further down there is congestion.

There is one more symptom of a preturberculous condition to which I would like to allude, and that is located in the larynx. This is a thickening of the interarytenoid space, which occasionally is very marked.

Repeatedly cases have been referred to me on account of "hemorrhage from the lungs" in which thorough examinations of the chest by competent medical men and examination of the sputum have revealed nothing tangible. Laryngoscopically, I found in these cases a bleeding spot in the trachea.

It is to be considered a fortunate thing for the tuberculous subject if hoarseness sets in at an early stage of the disease. If changes are visible within

*Read before the Metropolitan Medical Society February 22, 1910.

†W. Freudenthal: "On the Ætiology of Pulmonary Tuberculosis in Its Relation to Diseases of the Nose and Throat," *New York Medical Journal*, Dec. 19, 1903.

the larynx, they should put us on guard. A persistent hoarseness due to simple laryngitis that is not due to alcoholism or any constitutional disease like rheumatism, gout, etc., and does not yield to rational treatment, should be regarded as most likely tuberculous in character.

During the last few years the writer saw three cases in which the first and only sign of tuberculosis was a paralysis of the left vocal cord. They all were referred to him by their physicians on account of hoarseness. Invariably they felt perfectly well, and absolutely nothing else was discovered except that paralysis. It is needless to state that those patients were thoroughly examined, and that the existence of all other diseases, as lues, tabes, etc., was excluded. They showed signs of tuberculosis later on. Undoubtedly we had to deal in these cases with a latent tuberculosis that suddenly developed an activity in the cervical lymphatic glands, thus causing pressure on the superior laryngeal nerve.

And now only one word more about "laryngeal crepitation." When the ear is held close to the mouth of a patient while he is breathing you hear, according to Cybulski, as mentioned by Skillern, a sound resembling that of the scratching of a pen. This symptom, to which Cybulski and Skillern seem to attribute great significance, the writer has never been able to elicit in the early or pretuberculous stage of the disease, but generally much later. It then sometimes conveyed the sound of boiling water, and must be regarded as a very unfavorable symptom.

While it would seem absurd to make a diagnosis of pulmonary tuberculosis from the mere presence of hypertrophy of the lingual tonsil, or from a pronounced pallor of the mucosa of the hard palate, yet many or all of the above symptoms, taken collectively, in conjunction perhaps with the history of the case and certain suspicious pulmonary signs, will in many instances enable you to determine with great probability the existence of a tuberculous process in the lungs.

A CASE OF PELLAGRA IN ILLINOIS.

By WILLIAM FRANCIS WAUGH, A.M., M.D.,

CHICAGO, ILL.

PROFESSOR OF THERAPEUTICS BENNETT MEDICAL COLLEGE.

Edward L., aged 36 years, born in Illinois, of which State he has been a resident since birth. He is a farmer and lives in Marion county. He is not addicted to alcohol, nor has he been affected with syphilis, gonorrhea, or malaria.

In January, 1909, Mr. L. was seized with gastric and digestive troubles for which he was attended by Dr. John Akester of Farina, Ill. He noted in L.'s case the absence of any apparent cause for the digestive affection, its obstinacy, being unaffected by treatment or diet, and the unusual bodily prostration and mental depression present. Improvement followed that could not be attributed to the treatment, and relapses without obvious cause. Recognizing in the case something unusual, Dr. Akester brought the man to Chicago in April of this year. The patient was then emaciated, despondent, irresolute; affected with insomnia and neuralgic pains, atypical and variable; diarrhea, severe burning in the stomach, and in the mouth when aphthous ulcers were present, salivation not attributable to mercury, the diarrhea assuming the lienteric type; his nose was red, fissured, and rough, with an eruption resembling a chronic eczema, and his neck exhibiting a red collar resembling sunburn, but marked where the skin was protected against the sun by his beard. The prostration and emaciation were such as to induce a tentative diagnosis of tuberculosis, but this was not confirmed by physical examination or by tuberculin injections. Examinations of the blood, feces, and urine proved negative.

About the first of June an eruption appeared on the backs of his hands so characteristic as to confirm the diagnosis of pellagra. The dorsa of both hands appeared as if scalded, the surfaces were red and raw, the backs of the fingers fissured and rough up to margins of the nails which appeared unusually white, the eruption ending by a sharply defined margin at the wrists but extending completely around these. The palms were unaffected except as to being yellowish. The psychic depression progressed until the man made an attempt at suicide by slashing at the arteries in the wrist.

Before this occurred I had written to Dr. Akester suggesting the diagnosis of pellagra, and he replied that he had spoken of this possibility when he brought the patient to Chicago, though not to me. He is entitled to the credit of having been the first to detect a case of pellagra in Illinois, and I believe in the North, developing outside any public institution.

The four groups of symptoms are well-marked—the digestive, obstinate diarrhea uninfluenced by diet or drugs, intense burning in the stomach, aphthous ulcers with salivation in the mouth, emaciation and profound prostration; the cutaneous, the dorsal surfaces of the hands scalded, the nose roughened, the characteristic collar; the nervous, marked vertigo early in the disease and persistent, insomnia, wandering neural pains, uncertain gait but not ataxic; and the psychic, great mental depression and feebleness, with suicidal tendency.

Mr. L. tells us that there are at least two other persons in his vicinity similarly affected. The corn there has for some years been subject to a disease of the stalks, a form of mould extending from the roots through the stalk to the cobs and to some of the grains, which are shrunken and blackened. This is seen also in the other cereal grains raised in that locality. I have seen corn growing in Chicago similarly affected.

If this is indeed a case of pellagra it is important that physicians in the State shall be ready to recognize it as such in the earlier stages when, if ever, it may prove amenable to treatment.

The treatment of pellagra has not as yet been settled by conclusive beneficial results obtained from any remedy or method. Arsenic in the form of atoxyl has been commended, but there is a disquieting resemblance in these cases to some forms of arsenical poisoning; and it seems desirable that the remedies tested should be those that may be safely pushed to the production of full effects, since it is uncertain how much may be required.

The view of pellagra that assigns the symptoms to a gastric or intestinal mycosis does not seem in accord with the clinical picture presented, although there may be something of this element; and the routine practice of clearing the bowels and disinfecting them, which has proved so useful in other febrile maladies, need not be omitted. Dr. Akester has been giving copper arsenite, but I have advised the use of copper sulphocarbolate—copper because

of the great value of this metal in ridding drinking water of algæ and other vegetable growths, and the acid on account of its great powers as shown in the sulphocarbolates of zinc, lime, and soda. Of these I have prescribed for L. half a centigram every two hours, to be increased until some effect is manifested.

The most probable hypothesis assigns the symptoms to a mycosis of the tissues, and the analogies are with thrush, diphtheria, and tetanus. Hence I would suggest the administration of phenol, five centigrams daily in solution, hypodermically, injected intramuscularly. This is being given and proves unirritating. This will be continued until smokiness of the urine shows a destructive action on the red blood-corpuscles.

Meanwhile all the resources of the roborant régimé are being brought into operation—diet, exercise of passive kinds, fresh air, moral encouragement, iron, quinine, and strychnine in moderate dosage, and rubbing the body with hot oils every day. The open sores are relieved by applications of zinc ointment.

1358 Fulton Street.

A USEFUL ACCESSORY IN THE TREATMENT OF VARICOSE ULCERS.

By EUGENE H. POOL,
NEW YORK.

A scourge of varicose ulcers infests every clinic in which there is the slightest pretense of treating this distressing condition. How irksome both to the physician and patient the treatment becomes is well known to all who have worked in such a clinic.

The treatment usually employed consists in cleanliness and support of the leg, with appropriate applications to the ulcer, and in some cases surgical procedures.

The marked venous stasis and edema which accompany many of the old and refractory cases of ulcer diminishes the vitality and resistance of the tissues. That the stasis is generally credited with playing an important part in delaying the reparative process and in rendering treatment disappointing is evidenced by the efforts which are directed toward overcoming it. To this end no effort is spared to obtain support and pressure by strapping and by firm, smooth bandaging; its importance is likewise shown by the relatively rapid improvement which usually follows rest in bed with elevation of the limb in this class of cases. But the otherwise good health of the patient and the inability to give up work usually prevent the adoption of this last means of treatment. The endeavor to obtain a worthy substitute for rest in bed, one which will overcome venous stasis better than the means usually employed, gave rise to the method of treatment here described.

The worst cases in our clinic at the New York Hospital Dispensary have been taken as tests. The procedure is as follows: At the time of the dressings, three times a week, the patient is made to lie on the back on the examining table with both legs elevated almost to a right angle and supported against the wall; the patient lies in this position for about fifteen minutes. For the first few treatments massage is administered, stroking the limb toward the trunk. Before lowering the legs they are cleansed and dressed in an appropriate manner by strapping, medicinal applications, etc., and a muslin bandage is applied tightly and smoothly. The patient is instructed to resume this position three times a day for fifteen minutes each time, and at other times if the bandage feels too tight. No complaints have been made concerning the discomfort of the position and very few as to the tightness of the bandage. All the patients have expressed themselves from the outset as very much pleased with the results, stating that the legs are not only more comfortable, but show a more marked disposition to heal than by other methods.

By this method the engorgement of the veins and lymphatics is prevented and the edema diminished, as is evidenced by rapid diminution in the diameter of the legs after a brief period of treatment. Occlusion of the deep veins, of course, contraindicates the tight bandaging.

It must be emphasized that the method is intended to supplement and not as a substitute for other procedures. It will simply expedite the response of the tissues to curative agents. Appropriate local treatment must be as assiduously pursued as when this method is not followed. The only departure from the usual routine which is here suggested is the detail of elevation which seems to enhance the effect of the bandaging.

The following are brief summaries of three cases:

Case I.—Mrs. B., a large, fat woman, aged 47, came to the New York Hospital Dispensary on March 12, 1910. She could walk only with difficulty on account of pain in the right leg. She had been struck on the leg five months previously and an ulcer developed on the anterior aspect 4 inches above the ankle. The whole leg was greatly swollen and edematous, measuring 21¼ inches around the calf; above the ankle the flesh was in folds. The skin of the leg was tender, the subcutaneous tissues were hard and edematous, pitting slightly under pressure. The ulcer was superficial and healthy, 1½ inches in diameter. She received twelve treatments as outlined above. The ulcer healed rapidly and the size of the leg quickly diminished. On her discharge, April 12, the calf measured 16¾ inches, a diminution of 4½ inches in one month. The pain and difficulty in walking had entirely disappeared.

Case II.—Miss T., aged 27, came to the Dispensary April 27, 1909. She had been operated upon elsewhere for varicose veins one year before. Her legs were very painful, greatly swollen, and edematous; the right calf measured 19½ inches, the left 19⅝ inches. There was no ulceration. Under treatment as above described, consisting of elevation, massage, and bandaging the pain quickly subsided. On July 29 the legs measured 14½ inches and the patient was comfortable. She stopped treatment. On March 5, 1910, she again reported, and it was found that the legs had returned almost to their original condition, measuring 18¼ inches, and being painful.

Case III.—Mrs. O., a very large, fat woman, aged 53, came to the Dispensary on March 5, 1910. She had had varicose ulcers of the right leg for twelve years, and had received various treatments, including a course such as is here described, one year ago at the New York Hospital Dispensary. She improved at that time, but was obliged to cease treatment before cured. On admission the whole leg was greatly enlarged, hard, and tender. There was marked eczema of the leg and a large indolent ulcer with raised and hard borders. On April 19

the leg had shown a decided improvement, not so much in diminution of its size as in reduction of the area of the ulcer, which was reduced about one-third. The induration had disappeared except in close proximity to the ulcer. The patient was comfortable and wanted to continue treatment.

A CASE OF URTICARIA CAUSED BY THE SUN'S RAYS.

By BENJ. F. OCHS, M.D.,

ADJUNCT ATTENDING DERMATOLOGIST LEBANON HOSPITAL, DERMATOLOGIST LEBANON HOSPITAL O.P.D., ASSISTANT DERMATOLOGIST HARLEM HOSPITAL.

Urticaria is classified among the common dermatoses, and has many etiological factors—thus from the ingestion of many different food stuffs, as berries, clams, lobsters, cheese, etc., from different drugs taken internally as opium, quinine, and the coal-tar derivatives; from drugs used externally, from the antitoxins, from the bites of insects, etc. But to have an urticaria caused by the sun's rays only is exceedingly rare, and the following case is therefore thought of enough interest to report.

Mrs. M. W., æt. 34, married twelve years, had a miscarriage at the third month of her married life and has never been pregnant since. She attends to her own housework and always enjoys the best of health, the bowels and menses are regular, and her sleep is not disturbed. For the past nine years the patient notices that whenever she exposes any part of her body to the sunlight, she develops an urticaria. It matters not whether an arm, leg, or the face is exposed the urticaria is sure to follow. This urticaria is in direct ratio to the effect of the light; thus on a dark day with little sunlight, the urticaria is slight, while on bright sunny days the urticaria is very pronounced. The patient has called at the office several times with no urticaria and when the arms were bared and exposed to the sun's rays, decided urticarial wheals appeared in a few moments. This same thing was noticed time and again. However, when the patient used a dark-green or black umbrella and wore dark gloves to shield herself from the sun, no urticaria appeared. In order to test whether this urticaria was produced by any food ingested or only due to the sunlight, she was asked to eat liberally of such food as might cause urticaria, and at the same time to shield herself with a dark umbrella, but no urticaria developed; but when she exposed any part to the sun the urticaria appeared. The patient disappeared from treatment as there was no improvement from tonics, etc. This case is the more interesting because it is usual that the sun causes only a slight erythema in sensitive skins, and if the skin is exposed too long or is excessively sensitive, there is a decided burn, but to have it cause only urticarial wheals is exceedingly rare and the reporter thought this could be designated as a case of urticaria caused by the actinic rays of the sun.

1980 Seventh Avenue.

An Epidemic of Noma.—Neuhoff concludes a study of an epidemic of noma by saying "Noma usually appears in epidemic form, its contagiousness has not been proved. The disease is an entity, and not a later stage of ulcerative stomatitis; the latter offers a good soil for the development of noma. There is regularly present in noma a streptothrix characterized by a thick meshwork of mycelium at the border line between normal and necrotic tissue, fine rods and spirilla extend from mycelium into the adjacent tissues. The constant presence of this streptothrix to the exclusion of other organisms indicates that, in all probability, it stands in direct etiological relationship to noma. The streptothrix is present in noma before the disease is fully manifest—in the pregangrenous stage. It is in this stage of the disease that radical treatment is to be practised; after the ulcers spread, the best results are obtained by conservative measures. General anesthesia should not be employed in any form of treatment because of the pronounced tendency to the development of septic pulmonary disease."—*The American Journal of the Medical Sciences.*

The Streptococcus of Scarlatina and the Reaction of Fixation.—Ch. Foix and Et. Mallein say that after an important and remarkable series of experiments Gabritchewski has isolated by hemoculture a streptococcus with special characters of virulence and agglutination, which he regards as the cause of the disease. The authors in 12 cases obtained 83 per cent. of positive agglutination tests with the streptococcus isolated from the throats of scarlatinous children. They believe that here is an important differential characteristic between the streptococcus of erysipelas and of scarlatina based on this, and give the following conclusions. The serum of scarlatinous children contains antibodies active against the streptococcus of the scarlatinous throat; this is found early and in the late stages of the disease; the reaction of Bordet is absent in the other streptococcemias, while present in scarlatina; it may serve to establish a serodiagnosis; we do not yet know whether this is a specific reaction. Schliessner has obtained similar results, showing 81 per cent. of positive reactions.—*La Presse Médicale.*

The Importance of Blood-Pressure in the Toxemis of the Latter Half of Pregnancy.—J. C. Hirst lays down the following rules: (1) The normal blood-pressure, in normal, healthy, nonpregnant women, will not vary much from 112 mm. (2) The normal blood-pressure in healthy pregnant women will average close to 118 mm. A slight increase over these figures is to be expected in the last month of pregnancy. (3) Blood-pressure in toxemia in the first half of pregnancy, associated with pernicous vomiting, is invariably low. (4) Blood-pressure in toxemia in the latter half of pregnancy, associated with albuminuria and eclampsia, is invariably high. (5) A high and rising blood-pressure is an invariable and early, often the earliest, sign of toxemia in the latter half of pregnancy. (6) Upon the rupture of the membranes, there is an immediate fall of pressure of from 60 to 90 mm. This fall is temporary only, but is attended with marked relief in the headache and epigastric pain these patients so frequently complain of. The relief from these symptoms lasts, however, for some hours after the pressure returns to near its original height, which it does shortly after the first fall. A similar fall, but much slighter, is noticed after a sweat bath. (7) There is a second fall of from 60 to 90 mm. after the child is born. This again is only temporary, and in from fifteen to thirty minutes, if a patient has not bled profusely, the pressure is back to somewhere near, but not quite to, its level before the birth. (8) Usually, in eclampsia, the pressure measures high for forty-eight hours after the birth, then begins to subside and reaches the normal of from 118 to 124 mm. in from seven to ten days after delivery. (9) As far as it is possible to lay down any rules in these cases, the author says that a blood-pressure of below 125 mm could be disregarded; a pressure of from 125 to 150 mm needs careful watching and moderate eliminative treatment; and that a pressure of over 150 mm needs usually active eliminative treatment, and will, in all probability, especially if it shows a tendency to climb higher, require the induction of premature labor.—*New York Medical Journal.*

Influence of a Diet Without Salt in a Case of Habitual Death of the Fetus.—Prouvost gives the history of a case in which the first two pregnancies resulted in normal, living children, but in whom there followed a succession of dead children. The mother desired living children, and was very much depressed by her inability to have living ones. The dead children were swollen and edematous. The author thought that he would try removal of salt from the diet of the mother, who was very fond of salt, on the theory that too much salt was retained in the blood of the fetus. He made the patient eat meals that were specially prepared without salt, eating only dinner with the family. This was continued for some two years, when the patient brought forth a living, healthy baby. Two years later the woman became pregnant again, and the diet was repeated with a similar result. If results can speak for the cause of such a condition, it seems evident that the mother was taking too much salt, and that, for some reason, it was retained by the fetus in excess, producing an intoxication.—*Bulletin de la Société d'Obstetrique de Paris.*

DIET IN TRAINING.

THE question of diet is of the first importance in the training of athletes, and concerning this matter widely divergent views have been expressed by various authorities. It is freely allowed that the opinions of old-time dictators on the best means of feeding those in training for the exertion of severe physical efforts have been for the most part overturned. The diet in vogue in such cases forty or fifty years ago would not meet with favor in these days. Possibly the pendulum has swung too far in the opposite direction and a certain amount of faddism has been introduced into the subject. Yet it appears to have been definitely proven that youths and men can be brought into excellent physical condition, and kept in that condition, on foods which would have been regarded with the greatest suspicion in days of yore. For instance, there are many formidable athletes nowadays who are vegetarians. Mr. Eustace Miles, one of the best tennis players who has ever lived, is a rigid vegetarian. There are also those who confine themselves to a diet of fruits or nuts and who seem to be able to maintain a satisfactory bodily condition. In the face of varied and contradictory experiences, it must be confessed that one cannot yet make a dogmatic statement with regard to diet for athletes.

H. I. Gillett read a paper on diet in training before the Oxford Medical Society in the Radcliffe Infirmary, Oxford, on June 17. He pointed out that the majority of Oxford rowing men consume on the average 169 grams of protein daily, thus exceeding Atwater's standard of 150 grams daily for those doing severe muscular work. Liebig taught that the oxidation of proteins was the sole source of muscular energy; hence the diet formerly consisted largely of flesh. But now carbohydrates and fats are recognized as sources of energy, and a high protein diet is regarded as unnecessary or harmful. Atwater and Bryant, in their dietary studies in university boat crews, estimated that the average amount of protein consumed daily was 155 grams. They did not show that it was necessary to take so much, but they said that the diet best suited to training had not been decided upon, and so it varied according to the ideas of special trainers. Chittenden, on the other hand, does not follow the ideas of trainers or tradition, but has proved, at any rate to his own satisfaction, that athletes could keep in good condition and compete on favorable terms with others on as little as 55 grams of protein daily, the amount of protein varying with the weight of the individual. Gillett thought that Chittenden's estimate of the quantity of protein needful too low and suggested that in order to ensure nitrogenous equilibrium it would be safer to allow a considerably larger amount. Excess of protein is bad, in that it must mean unnecessary work for the digestive organs, liver, and kidneys, and the purins may cause symptoms of general malaise and irritability and throw extra work on the organs of excretion. Toxemia may result from decomposition of protein, causing a high blood pressure with consequent strain on the heart, in addition to the strain of exercise. The point is how to discover what constitutes an excess of protein and to find out whether a hard and fast rule can be laid down with respect to the diet of athletes. Judging from experiments and tests which have been made up to the present time, it may be stated with emphasis that no arbitrary rule can be deduced from these and it seems likely that the diet of athletes must be regulated according to the idiosyncrasies of individuals under the direction of medical men or skilled trainers. A medical trainer should not take long to find out whether his pupils are suffering from an excess of protein or, at least, he should be able to ascertain with a sufficient degree of exactitude, after a few weeks' observation, whether their diet is suitable. The personal equation, after all, must be considered, and it does not appear reasonable to suppose that a routine diet can be ordered that will be suitable for each and every athlete.

TREATMENT OF LUPUS.

THE report of the committee on the treatment of lupus of the German Central Committee for Combating Tuberculosis was made public orally on May 12 last, in Berlin, and has now appeared in the *Deutsche medizinische Wochenschrift* of June 23. It cannot be justly maintained that lupus is *per se* an affection of much interest to the great body of American practitioners, for it occurs principally in immigrants from Europe, and is seldom seen save in large cities, and then chiefly in hospital practice. We refer to typical lupus of the face, for atypical tuberculous lesions which technically might be classed as forms of lupus are seen now and then in native Americans, often giving rise to much speculation as to their intimate nature. The inoculation-lupus on the hands of butchers might be cited in this connection; also so-called ulcerating scrofulides, and tuberculous gummata, which develop either spontaneously or in association with tuberculous sinus discharges All these lesions differ notably from classical lupus of the face and contiguous muscosæ, with which we assume the German committee is primarily concerned.

In the report in question Professor Lang takes up the surgical treatment proper, which refers chiefly to extirpation of the focus with resulting plastic operation. He recommends this as the pro-

cedure of choice in suitable cases, and free from the objections native to the Finsen treatment, which requires an elaborate outfit and much time and trouble. Professor Zinsser of Cologne reports on the Finsen method, the chief advantage of which is bound up in the demonstration of the absolute curability of lupus by mild measures. Wickmann of Hamburg follows with the radium treatment of lupus. He claims that it represents an advance in our resources and that it is specially to be recommended in small disseminated foci where excision is contraindicated, and also in lupus of the mucosæ. He does not draw any parallel between the Finsen and radium therapy. The number of cases treated with radium is probably too small for comparison with other methods (only 23 cases are mentioned). We derive the impression that radium therapy is worth while chiefly as a procedure accessory to other methods. Gottschalk of Stuttgart considers all other methods of treatment jointly. These include radiography, the Kromayer lamp, tuberculin, and chemical remedies.

As was to have been expected, the discussion which followed these reports was best adapted to reveal the state of professional opinion, but this proved to be very contradictory. Each method had its advocates. Neisser, for example, is a believer in radiotherapy plus tuberculin. Several others commended pure surgical measures because of their practical adaptability to the time and purse of patients. Others, by reason of the smooth cosmetic results not attainable through autoplasty preferred some form of light treatment. No consensus of opinion can be said to have been reached, save the obvious ones of selection of the remedy best suited for the individual case, and of combination of remedies whenever possible.

Operative Treatment of Spastic Diplegia.

The spastic diplegias resulting from upper neuron lesion, especially of the newborn, are conditions which until recently have been but very slightly amenable to treatment. The loss of the inhibitory action of the cortical centers upon the motor cells of the spinal cord while the lower neurons are uninjured and are constantly being stimulated by the sensory impulses received from the posterior root nerves, causes the continuous and uncontrolled production of efferent impulses through the anterior roots and the consequent reflex muscular spasms. The results of tenotomies, myotomies, and tendon transplantations have in some cases improved the function of the affected limbs, but more frequently the real benefit derived from such operations has been slight indeed. In 1907, however, Foerster of Breslau recommended a new procedure in such cases. On the theory of the spasm being due to the reflex overactivity of the motor cells of the lower neuron by the uncontrolled stimulation from sensory impulses, he suggested that, if the latter were reduced by cutting some of the sensory roots, the spasm might be decreased without injury to what voluntary or reflex motor power still remained in the affected parts. In the *Deutsche medizinische Wochenschrift* for May 12, 1910, Hevesi reports a successful result from this operation in a girl eleven years of age who had been a spastic diplegic since infancy. With the patient lying on her face he opened the lower end of the spinal canal, incised the membranes, and with a blunt hook elevated the nerves of the cauda equina corresponding to the second, third, and fifth lumbar, and second sacral posterior roots on the left side and the second and fourth lumbar and first sacral on the right side. From each of these nerves he excised a piece varying from 2 to 6 cm. in length. The wound was closed temporarily and the next day the dura, muscles, and skin were firmly united in layers and a small drain was inserted for two days. The wound healed *per primam* and the child made a good recovery from the immediate effects of the operation. Six weeks later walking was attempted with support, and during the seventh week the child began to walk by herself with slow steps and bent hips and knees. There was no spasm, no ataxia, and no gross loss of sensibility in the legs. The operation made further training possible by exercises, which previously the spastic condition had prevented. This operation has now been performed a number of times in such cases, and from the reports which have appeared it would seem to be the most successful method of treating spastic diplegia yet adopted.

Conservation of Human Life in Pennsylvania.

The Pennsylvania Health Bulletin for March shows the results of the work that has been done by the State Department of Health during the past four years in the conservation of public health. In this period three million dollars have been expended, resulting in a saving of twenty-three million dollars to the commonwealth. By reason of the State supplying diphtheria antitoxin for the poor the lives of thousands of little children have been saved. Fewer persons are being killed by typhoid fever in Pennsylvania than was the case four years ago, and the death rate from tuberculosis is considerably less. This is stated to be the visible outcome of the generous appropriation made by the State of Pennsylvania in the interests of public health. For example, since October, 1905, the Health Department has distributed for use among the children of the poor 49,443 packages of antitoxin. It has treated 19,929 sick people, mostly children, who, but for the State's intervention, would have been neglected. The department in three years has immunized with antitoxin 14,527 persons, nearly all children, who had been exposed to the disease. Again in four years the death rate from tuberculosis in the State has fallen from 134 to 120 per 1,000 inhabitants. Free tuberculosis dispensaries have been established and a tuberculosis colony has been founded at Mont Alto. A second State sanatorium is to be established at Cresson and a third institution in the foothills of the Blue Mountains near Hamburg. Perhaps, however, the most important work done by the Health Department has been in connection with typhoid fever. In 1905 the State Legislature recognized the necessity for central control of the water supplies, and placed all water courses, so far as public sanitation was concerned, under the jurisdiction of the Governor, Attorney-General, and Commissioner of Health. Of course this simplified matters greatly. Whenever a case of typhoid fever is reported the department can immediately trace it to the watershed where it originated and investigate accordingly. The Department has been invested with very broad powers, and acting through these, by means of its army of inspectors, has pene-

trated the remotest recesses of the State, inspecting premises, noting palpable nuisances, and investigating water and sewerage systems. It is stated that already the typhoid fever rate has been reduced by half owing to these improvements. As we have often insisted, it is only by cooperation between State, municipal, and health authorities, aided by the earnest good will of the community, that real results can ensue.

The "Leg Phenomenon" in Tetany.

A few months ago Schlesinger of Vienna demonstrated, in a patient suffering from tetany, a symptom in many ways similar to the Trousseau sign, but occurring in the leg instead of the arm. The new symptom, which the author considered to be pathognomonic of tetany, consisted in the production of an extreme supinatory spasm of the foot by simultaneous extension of the knee and flexion of the hip. The symptom could be elicited either by raising the leg aloft, while the patient lay on his back, by having the patient sit up in bed, with the legs stretched out straight, or by having him bend his body forward while standing erect. In the *Deutsche medizinische Wochenschrift* for June 2, 1910, Alexander of Berlin discusses the subject of this new symptom of tetany, and endeavors to explain it. In the case which he reports the symptom was elicited with ease, but during the spasm he observed that the pulse in the feet was in no way decreased in strength, from which fact he deduced that the phenomenon could not be the result of pressure on the artery, as is supposed to be the case in the Trousseau sign in the arm. He believes, on the other hand, that the cause of the phenomenon is the stretching of the hypersensitive sciatic nerve over the tuber ischii. Further proof of this appeared in the fact that bandages around the thighs, sufficiently tight completely to obliterate the pulse, but not causing stretching of the nerve, failed to produce the symptom. Furthermore, in two infants with marked tetany the phenomenon could not be produced, probably due to the fact that the physiological position of the infant *in utero* being such that the thigh is in extreme flexion, the artificial production of a similar position during early life causes no undue tension on the nerve. Again, experimenting with the Trousseau symptom the author found that in persons suffering from tetany the typical spasm of the arms and hands could be produced by merely raising the arms and holding them in contact with the ears, and that in such a position, while the nerve trunk is stretched over the head of the humerus, the intact radial pulse proves that obliteration of the brachial artery has not been produced. These findings all point strongly to nervous origin of the Trousseau sign and this new phenomenon, rather than to their production by obstruction of the blood supply to the limbs. Whatever the explanation may be, the practical value of the leg phenomenon for the diagnosis of adult tetany promises to be considerable.

"Albumin-Milk" in the Diarrhea of Nurslings.

Finkelstein and Meyer, of the Berlin Foundling Asylum, have been seeking to combat infantile diarrhea by a milk modified as follows: Wishing to get rid of the lactose and saline matter, they curdle one liter of milk and strain out the casein and fat. The latter are then added to half a liter of plain water; and to this is further added an equal amount of buttermilk. The resulting modification is poor in lactose and salts and rich in casein and fat. This milk is given to all foundlings which have diarrhea, whether mild or severe in type; to all previously healthy who develop indigestion, and to children with gastroenteritis with impending marasmus. The rationale of this dietetic resource lies obviously in the belief of the authors that the fermentation of the lactose either plays a marked role in causing diarrhea or else tends strongly to antagonize recovery. It does not appear, from the present paper, at least, that the saline matter is directly accused of contributing to the diarrhea, but this and milk sugar constitute the strictly soluble contents of the whey, and in getting rid of the sugar we must at the same time get rid of the salts. However, it is alleged in some quarters that the unnatural element of cow's milk for infant feeding resides not in its casein and fat, but in the serum or whey as a whole. This is not to be eliminated completely, but cut down to such quantity as the human organism can take care of. The milk is not designed for indefinite consumption, but only as long as indicated.

News of the Week.

To Study Ambulance Systems.—At the request of the Police Commissioner of New York, Mr. William I. Spiegelberg, president of the Sydenham Hospital, who sailed recently to study private and public hospitals in various European cities, will also investigate the different ambulance systems. Mr. Spiegelberg is chairman of the Ambulance Committee of the City of New York.

Army Medical School.—The War Department has issued an order establishing a field service school for army medical officers, as a part of the army service school at Fort Leavenworth, Kan. The object of the new school is to prepare officers of the Medical Corps and medical officers of the organized militia for the better performance of their duties as administrative and staff officers on field service and to make research into such subjects as may concern medical officers under field conditions. The course of instruction will cover a period of not less than six weeks, beginning on April 1 of each year. The senior officers of the new school will be the Commandant and Secretary of the Army Service School, and the Assistant Commandant will be an officer of the Medical Corps with a grade not lower than that of major. Student officers will be selected by the Surgeon-General of the Army.

Census Figures.—Rhode Island is the first State to have its census returns completed. The official count of the population is 542,674, an increase of 114,118 or 26.6 per cent. over the figures for 1900. The increase during the preceding decade, 1890-1900, was 83,050, or 24 per cent.

City Docks for Sick Children.—The Dock Commissioner of New York has announced a plan for utilizing the unused space in the city ferry terminal buildings at the South Ferry as open-air hospitals for sick children. In each building a space 75 x 100 feet would be available, and could be fitted with cots, etc., if the city should see fit to appropriate the necessary money.

Bellevue Appointments.—Dr. Michael J. Thornton has been appointed assistant alienist at Bellevue Hospital, New York, to succeed Dr. Mark L. Fleming, recently appointed second assistant medical superintendent. Dr. Thornton was graduated from

the Albany Medical College in 1901, has been connected with various insane asylums, and has been mental examiner at Ellis Island for the past four years. Miss Clara D. Noyes has been appointed director of nurses at Bellevue to succeed Miss Annie W. Goodrich who resigned recently to become State inspector of nurses' training schools under the jurisdiction of the State Department of Education. Miss Noyes is a graduate of the Johns Hopkins Hospital Training School and has had considerable experience in superintending such training schools, as well as in connection with the department of hospital economics at Columbia University.

Medical Reciprocity Between Italy and Great Britain.—Legislation has recently been enacted in Italy affecting the position of foreign medical practitioners in that country. Under this new law, British medical practitioners, in virtue of the reciprocity granted by Great Britain, will in the future enjoy unrestricted freedom of practice in Italy, instead of the limited rights hitherto conceded them of practising only among foreigners.

City Death Rate.—For the week ending July 16 the death rate in New York was 18.88 per 1,000 of population, a considerable increase over the same week in 1909, when the rate was 15.97. The total number of deaths was 1,705, against a total of 1,397 for the same week last year. Forty-five deaths were attributed directly to the heat. There were 785 deaths among children under five years, and 568 among infants under one year. Typhoid fever caused fifteen deaths, seven more than a year ago, and pneumonia 115, seven less. The 181 deaths from tuberculosis were an increase of 23 over the total from this disease in the corresponding week last year. Even deaths from violence increased, 162 being recorded, against 93 a year ago.

Mr. Arthur MacDonald of Washington, D. C., was elected an honorary member of the Medico-Legal Society of New York City at a meeting of the society held recently.

Dr. John B. Byrne, Jr., of Brooklyn has been appointed private clerk to Coroner Rooney of that borough. A law passed a few years ago empowered the coroners to make such appointments, at a salary of $1,500 per year, but the predecessors of the Brooklyn coroners have been unable to act since the necessary appropriations were not made until recently by the Board of Estimate. Coroner Glinner of Brooklyn has appointed Mr. Thomas Creamer as his private clerk.

Bequests to Charities.—The Seney Hospital and the Methodist Home for Aged People in Brooklyn, N. Y., each receive $5,000 under the will of the late Charles P. Armstrong, who died recently at Greenwich, Conn.

The Maine Medical Association.—At the recent annual meeting of this society held at Bar Harbor, the following officers were elected for the ensuing year: *President,* Dr. E. H. Bennett of Lubec; *Vice-Presidents,* Dr. Addison Thayer of Portland, and Dr. F. M. Whittier of Brunswick; *Secretary,* Dr. W. Bean Moulton of Portland; *Treasurer,* Dr. E. W. Gehring of Portland; *Councilors,* fifth district, Dr. R. W. Wakefield of Bar Harbor; sixth district, Dr. R. H. Marsh of Guilford. The fifty-ninth annual convention of the association will be held in Augusta on the last Wednesday and Thursday of June, 1911.

The Austin Flint Cedar Valley (Iowa) Medical Society.—At a meeting of this society, held on July 13, at Mason City, Ia., the following officers were elected for the coming year: *President,* Dr. Paul E. Gardner of New Hampton; *Vice-President,* Dr. J. C. Powers of Hampton; *Secretary,* Dr. C. F. Starr of Mason City; *Treasurer,* Dr. W. L. Hearst of Cedar Falls. The next meeting will be held in New Hampton.

The Rutland County (Vermont) Medical and Surgical Society.—The annual meeting of this society was held at Lake Bomoseen on July 12. Dr. G. G. Marshall of Rutland was elected president of the society for the ensuing year, and Dr. William Stickney of Rutland was elected secretary and treasurer.

The Medical Library Association.—The thirteenth annual meeting of this association was held in St. Louis on June 6, the president, Dr. J. H. Musser, in the chair. The secretary's report recommended that the Association print the Constitution and By-Laws and a list of the members of the Association, and also that notification of dues be sent regularly to each member. On motion, the recommendations were approved. The report of the treasurer showed a balance of $43.33. The report of the manager of exchange stated that during the year the material belonging to the exchange, consisting of 11,919 volumes and 7,707 unbound numbers, reprints, etc., had been removed from Brooklyn to Baltimore. The following officers were elected for the ensuing year: *President,* Dr. John Musser of Philadelphia; *Vice-President,* Mr. C. Perry Fisher of Philadelphia; *Secretary,* Miss M. R. Charlton of Montreal; *Treasurer,* Dr. John Rurâh of Batlimore. The Lackawanna Medical Society Library of Scranton, Pa., and Dr. John Rurâh were elected new members. The meeting adjourned subject to the call of the executive committee.

Obituary Notes—Dr. Charles N. Hewitt of Red Wing, Minn., died in Summit, N. J., on July 7, aged 72 years. Dr. Hewitt was graduated from the Albany Medical College in 1857, and in 1861 enlisted in the Fiftieth New York Engineers as assistant surgeon, later becoming surgeon-in-chief of the engineer brigade. At the close of the war he was breveted a lieutenant-colonel, and removed to Minnesota where he practised until his retirement a few years ago. In 1872, when the State Board of Health was organized, Dr. Hewitt was made executive secretary, an office which he held for 25 years. He was at one time president of the American Public Health Association, and was an associate of the Society of Medical Officers of Health of England and of the Société d'Hygiene of France. For some twenty years he held a non-resident professorship of public health in the University of Minnesota. He was also a member of the American Medical Association and of the Minnesota State and Goodhue County Medical Societies.

Dr. Leslie Dodd Ward of Madison, N. J., Vice-President of the Prudential Life Insurance Company, died in London, England, on July 13, of acute kidney disease complicated with pneumonia, in the seventy-fifth year of his age. Dr. Ward was graduated from the College of Physicians and Surgeons of New York in 1868, and after some time of service as County Physician of Essex County, New Jersey, became interested in the question of life insurance, for many years serving as chief medical adviser in the company of which he afterward became one of the principal officers. In 1884 he relinquished his practice in order to devote all his time to the work.

Correspondence.

THE FUNCTION OF THE CORPUS LUTEUM.

To the Editor of the Medical Record:

Sir: Your issue of June 25, 1910, just to hand, contains an article, being a summary of original research, on this subject from the pen of Professor Leo Loeb. On page 1086 we read: "Thus far we had progressed in our work, when we found in the literature a communication by J. Beard in which this author gave expression to the hypothesis that the corpus luteum might have the function of preventing the rupture of the follicles during pregnancy. He did not undertake to prove this suggestion, and his hypothesis does not absolutely correspond to reality. The corpus luteum has a wider function than he conceived of; it not only prevents ovulation during pregnancy, but it delays ovulation also in nonpregnant animals. It changes the sexual cycle, a conception rather contrary to what Beard assumed. But, notwithstanding these imperfections in his hypothetical conclusions, we cannot but express our admiration for the scientific imagination of Beard. He has not received his due recognition, and what now has proved to be correct in his hypothesis we find in the literature without justification attributed to others—a mistake transmitted from one writer to another and a marked example of a not uncommon occurrence." In the first place, the reference given by Dr. Loeb is to a short paper in the *Anatomischer Anzeiger*, 1897, bearing the title "The Rhythm of Reproduction in Mammalia." This is merely a brief abstract of a small book of 132 pages published for me in 1897 by Gustav Fischer, Jena, under the title "The Span of Gestation and the Cause of Birth." The corpus luteum is mentioned on pages 82 and 118. As the full original paper is still on sale, it is not clear why Dr. Loeb refers merely to the author's abstract, published for the sake of drawing the attention of anatomists, physiologists, and embryologists to the former. Then, as a perusal of the complete paper would have shown, I was concerned only with the influence of the corpus luteum on ovulation, and in a paper treating of the Rhythm of Reproduction and the Span of Gestation there was no particular reason why other influences of the corpus luteum should be inquired into. Dr. Loeb now confirms this influence, and a very significant power it is, especially in the light of our present knowledge that the cells of the corpus luteum are sister cells of the egg, its degraded sisters, which provide for its welfare in the ovary and after fertilization. It is interesting and important to note the find of Dr. Loeb that the corpus luteum "delays ovulation also in nonpregnant animals." The research on the "Span of Gestation" revealed many, many things to its author, but, while it taught him that the "span" had been prolonged, and the ovulation intervals (units) also, it failed to disclose to him the mechanism of this latter. Now, in my opinion Dr. Loeb is right in saying that "it (*i.e.* the corpus luteum) changes the sexual cycle," but in error in adding the words "a conception rather contrary to what Beard assumed." His conclusions fit in remarkably with the results published in 1897 in my "Span of Gestation." I cannot feel other than grateful to Dr. Loeb for the words written in the latter portion of the citation from his paper, albeit—es lässt mich ganz kalt. It is not by any means an isolated instance in my career since 1882 to have my results and conclusions adopted by others without the least acknowledgment. This at times has happened to my mistakes also. Dr. Loeb has, I fear, yet to learn that all investigators are not like him and me, full of zeal for the advancement of science, but that sometimes the advancement of self takes the foremost place, and then the work of others may seem a legitimate spoil. There is also such a thing as verifying one's citations, the neglect of which may account for the "transmitted mistake" mentioned by him. I never met more than two other embryologists who had actually read Carl von Baer's big work on the "Development of Animals," "Entwicklungsgeschichte der Thiere," but I have seen scores and scores of "citations" from this classic work, and as a rule these were false. One embryologist once, and not so long ago, printed a paper on "von Baer's Law," neglecting to mention that von Baer laid down four laws of development, which at their basis are really two, and which do not include the "law" attributed to von Baer, who had indeed opposed it bitterly.

I would like to draw attention to Dr. Loeb's statement that the corpus luteum does not act on the wall of the oviduct, a fact with significant bearing upon tubal gestations and their consequences. The real import of the action upon the uterus I recognize in the production of a mass of tissue furnished for the trophoblast to act upon, instead of permitting it to erode its way through the uterine wall, when the consequences would be as grave as they are in a tubal gestation. From this Dr. Loeb will, I trust, see that even his latest results perchance do not reveal the full story. Did the corpus luteum not help the uterus to provide this nutritive cushion for the action of the trophoblast, it is certain that each one of us would in his own gestation, by means of a malignant "trophoblastoma" or so-called chorioepithelioma, kill his own parent, and in doing so bring about his own destruction.

On one occasion the writer reminded the editors of the *Lancet* that his findings and conclusions had at times an awkward habit of turning out to be true. It does not surprise me that Dr. Loeb now confirms, and extends, certain conclusions of mine enunciated thirteen years ago. The recognition that investigators of the scientific acumen of Dr. Leo Loeb exist and are extending the boundaries of human scientific knowledge is very comforting to one who at times feels somewhat of a veteran. Apparently, there is in the world still some science differing from the inane nonsense contributed—for payment—by anonymous authors, and transparent at that, on "cancer booms." In his present line of work Dr. Loeb is toiling in a rich and interesting region, as I know from old experiences. When he thinks of any little finds of mine there, he might also remember that there is an "antivivisection act" in this country, and that this explains more than one of my halts. He has encountered my footprints of thirteen years ago, and perchance they may lead him directly, as did the "Span of Gestation" me, to the problems of cancer. There also he may come to recognize how deservedly the writer earned not "recognition" but abuse and ridicule . . . for venturing to publish the truth for its own sake. For in my scientific opinion, based upon the results of "The Span of Gestation" and other memoirs, as well as upon actual results obtained in medical practice by others,* the only possible scientific treatment of malignant disease in general is by injections of sufficiently powerful preparations of both trypsin and amylopsin in proper dosage. What these scientific strengths and doses are and what results they produce in competent scientific hands may be left for description on an early occasion.

J. Beard.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

TUBERCULOSIS CONFERENCE AT EDINBURGH—EXHIBITION, HOSPITAL, FARM COLONY—DISCUSSIONS; AVENUES OF INFECTION; PREVENTIVE MEASURES—AMERICAN SURGEONS' VISIT—HUNTERIAN MUSEUM—VIVISECTION—OBITUARY.

London, July 8, 1910.

The Tuberculosis Conference mentioned in my last may certainly be considered a success, and Edinburgh has naturally attracted much of our attention all the week. No city could have been better chosen, and all her institutions have contributed to the result. In half a dozen of her schools distinguished experts addressed the teachers and senior scholars on the causes and prevention of consumption. It is estimated that more than 3,000 persons thus received some authoritative instruction. Lady Aberdeen urged on her young audience to lead healthy lives, in the hope that they would live to see the disease nearly fade out. About 1,000 visitors went to the opening of the farm colony for consumptive convalescents from the Victoria Hospital. The tuberculosis exhibition was largely attended. Dr. Halliday Sutherland delivered a popular lecture on "The White Plague," in which he compared the elaborate precautions against infection of less prevalent diseases with those taken against tuberculosis, with its annual death roll of 77,000. On Sunday there was a special service for students and guests, at which Professor Osler gave an address on "Man's Redemption of Man." He said the campaign was one of hope, as shown by history, and it was one of the triumphs of our generation to have determined the cause of the disease. The service concluded with addresses in memoriam, Robert Koch, delivered by Drs. Biggs, Woodhead and Philip. On Monday there was the annual meeting of the Association for the Prevention of Phthisis. Lord Balfour of Burleigh presided, and strongly urged local authorities to adopt compulsory notification, without which they were working in the dark. The disease had been diminishing in prevalence, if not in virulence, and must be tackled in earnest. The principal discussion was opened by Professor Sims Woodhead on

the avenues of infection, as to which he said there seemed to be a good deal of misapprehension because many of the experiments carried out concerning the power of infection had had more read into them than was justifiable. He held that the majority of cases were due to infection through the respiratory system, although he could not deny in the face of the early observations that a certain proportion occurred through the alimentary canal. In experimental work the great pitfall was the amount of infection. Unless this could be determined there must be considerable danger of error. Animals were more resistant than men, and in experimenting on them a maximum amount of infective material was often introduced far in excess of what might reach man in the ordinary conditions of practice. Again, postmortem appearances might mislead unless it were remembered that they were mostly only seen in the advanced stages—in fact, were the effects of past disease. Tuberculosis was so frequent that some had said that 90 per cent. of the population which arrived at forty-five years of age had been infected. He would put the percentage higher, as he thought almost everybody at some time or other had lodged the bacillus.

Professor McWeeney of Dublin said he adhered to the opinion that in the majority of cases of phthisis the infection took place through the lungs. Professor Adami of Montreal said it was difficult, often impossible, to speak with certainty, and he was not inclined to dogmatize. Opinion had veered round so much of late years that it behooved all to be cautious. Postnatal infection seemed the usual event, for if children were separated from infected mothers they were not attacked. Last autumn he inspected a school of 150 red Indian children, boys and girls, ages seven to sixteen, and was convinced that practically every one was infected before admission. But if so, the disease had been latent or extremely slow in progression for years before becoming acute—in some for ten years or more. Not one had been fed on cow's milk; all seemed to be due to human infection. He thought the chief avenue of infection was through the respiratory passages.

Dr. James Ritchie of Edinburgh was not prepared to admit that the work done so far detracted very much from the established pathological doctrine that the bacillus produced its first effect on the tissues at the point of entrance.

Dr. R. W. Philip of the Royal Victoria Hospital said he had reached the conclusion that, while the whole of the respiratory membrane was vulnerable, that in the region of the tonsils was the most vulnerable of all. That was the result of clinical observations, not only from month to month, but also from year to year. He suggested that every man's practice afforded him a field of observation and a laboratory in reference to this matter.

Professor Tendeloo of Leyden held that the infection was mostly through the lungs, but other avenues could not be ignored. Another discussion was devoted to preventive measures and administrative control. In this Dr. Leslie Mackenzie, representing the Scottish Local Government Board, said they desired to see every local authority well equipped with a triple organization of dispensary, sanatorium, and hospital, or their equivalents—in fact, the system which had worked so admirably in Edinburgh. Dr. Hope of Liverpool then pleaded for more systematic teaching of hygiene in the schools, and insisted that during such instruction the great importance of temperance should be impressed on the scholars.

The party of American surgeons who came to visit our hospitals have had, I think, a good time. They were entertained on arrival by the Council of the Royal College of Surgeons, were received by the President, Mr. Butlin, in the college and conducted round the Hunterian Museum by the Conservator, Professor Arthur Keith. Of course, they were received by your Ambassador, visited the House of Commons, had a look at London's cricket ground, and a number of other popular institutions.

The specimens added to the Hunterian Museum during the year have been on special view for the last three days. Many valuable gifts have been presented by the Imperial Research Fund, and I hear that numerous preparations made by the Royal Commission on Tuberculosis, illustrating the experimental production of the disease, will shortly be handed over to the custody of the college. The King has presented a hen pheasant assuming male plumage, which was shot at Sandringham. Yesterday the voting for the four Council vacancies took place at the college. The following were elected: Messrs. Lockwood, Polland, Bland-Sutton and Ballance.

Three cases of beriberi, which occurred on one of the war ships when in the Persian Gulf, have been invalided home, and arrived at Plymouth. Some suspicious cases were under observation at the time these left the vessel.

The death is reported of Col. L. O. Patterson, Royal Army Medical Department, who joined the service in 1854 and two years later took part in the Burmese war. He served through the Indian mutiny, being wounded at Sirchoon, was mentioned in despatches and awarded the medal. He retired in 1880.

Yesterday Viscount Goschen presided at the distribution of prizes at Guy's Hospital. Professor Howard Marsh, who presented them, said some of the most destructive diseases were being gradually wiped out. A new world of microorganisms had been discovered. When the public knew what advances had been made, and were told by such men as Lister and Paget that they had been gained in the only possible way, who was competent to contradict them? When no man could perform an experiment on an animal without a special license was not the matter in safe hands, and was any one who knew nothing of biology in a position to interfere with research and bring odious charges against those engaged in such work? Would not the public rather be grateful to those who did them this great service and extend to them full support?

Mr. Marsh's common sense is scarcely likely to affect the fanatics. A few days previously Mr. Walter Hadlow, M.R.C.S., was declaring at a drawing room meeting that he knew nothing in the whole realm of vivisection that had ever been of benefit in ameliorating or curing human disease. If he is equally ignorant of "the whole realm" of medical science he might do worse than go to school again.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

KOCH'S DEATH—A YEAR OF MEDICAL CENTENARIES—OPENING OF THE SECOND MEDICAL CLINIC OF THE CHARITÉ.

BERLIN, June 25, 1910.

The medical profession of Germany has been and is still at the present time under the burden of profound sorrow which was called forth everywhere by the death of Koch. It was generally known that he had just passed through a severe illness. But that he should have been so quickly taken from us would have seemed incredible shortly before the event to all who were familiar with his then healthy appearance. No one could forbode that this physique, steeled by so many voyages and hardened by such manifold privations, would succumb so quickly, albeit the time of life was advanced. The grief has become universal. Its eloquent expression will be found on great commemorative occasions in the future, and to-day we take advantage of this occasion to think of the Great Dead.

The year 1910, which in the autumn will bring about the centennial of the foundation of the University of Berlin, is at the same time a year rich in memories for the medical institutions. Last May the University Poliklinik celebrated its centennial. The director of this institution, Hermann Senator, gave in the course of a brilliant festival meeting a survey of the history of the Poliklinik. The latter was inaugurated by Hufeland in May, 1810, who had at his disposal three rooms in one of the wings of the university, with an equipment consisting of a few test glasses, a tongue spatula and an alcohol lamp. Eight years later a fourth room was added. Under Romberg, successor to Hufeland, the Poliklinik moved into quarters of its own. In the 50's of the nineteenth century, Joseph Meyer became Romberg's successor, and since 1887 Senator has directed the institution. Since 1905 the latter has possessed a building expressly constructed for its own use provided with the most splendid arrangements demanded by modern medicine for carrying out instruction.

In the earliest years the Poliklinik averaged 700 patients annually; under Romberg's direction 3,000, and at the present time 20,000. The great importance which this institution enjoys in the scientific world is closely bound up with Senator's activity. Doubtless he is the representative type of the Berlin University teacher. For years he had to seek his daily bread as a practising physician, but he never became oblivious of science. A certain quiet, one might say modest, definiteness never left him, not even after all the honors which accrue to a successful teacher in a medical institute became heaped on his head. This sounds like an echo. And, in fact, one could only listen at this time to this distinguished man with a certain sadness. For it was already known that in a few months he was to leave the seat of his long successful labors.

Shortly after this, the Charité Hospital celebrated the two hundredth anniversay of its existence, and at the same time the opening of its newly erected second

medical clinic. In the auditorium of the latter a great festival occasion was celebrated, and the medical director, General Physician Schaibe, delivered an address on the development and history of Charité Hospital. It was originally constructed for a pest house at the Berlin Gate; but as the plague spared the city the building was utilized as a hospital. In the middle of the eighteenth century a division of the building was used for the instruction of midwives. Its own purpose, however, was not fulfilled until the beginning of the nineteenth century; for it was arranged chiefly for the instruction of military medical men. Hence up to the present time a certain number of auxiliary and assistanceship positions were occupied by actual or prospective military physicians. Since 1897 the clinics and laboratories have been remodeled, so that now only the first medical clinic, the midwifery, and the second eye clinics remain for the time being in their original grey walls. In some 1,400 beds about 18,000 patients are received annually, and cared for by 200 physicians and 650 other employees. The Polikliniks are attended by 120,000 patients, and the annual expenses amount to about 2,000,000 marks.

The Second Medical Clinic was opened with an address given by its director, Strauss, on clinical management and clinical instruction. Only in connection with the university could the comprehension of the physician's calling be elevated, and thereby empirically acquired activity be made scientific and rational. Hence founding of institutions for clinical instruction has paved the way for a better period in medical practice. Distinguished medical men of the eighteenth century such as Boerhaave, Hoffmann, Stahl, etc., had no pupils; there were no scientific data in Berlin, and the most important innovations of the day, as percussion and vaccination, were known in Berlin only at a late day. The foundation of the University, with Hufeland's activity, changed all this. Schönlein, who became director of the clinic in 1839, was the first to give to instruction an exact scientific foundation. His successor was Traube, who erected in addition to the only clinic hitherto present a second propadeutic clinic directed first by Traube's pupil Leyden, and from 1885 to 1902 by Gerhardt, after the second clinic had been placed on the same plane as the original one. For the clinic as a whole three forms of activity came under consideration, viz.: the stationary hospital clinic, the ambulatory poliklinik, and the propadeutic clinic. In the first period of the existence of the clinic the Hippocratic ideas of emphasis on morbid general phenomena, etiological diagnosis, and physicodietetic therapy prevailed. The Paris-Vienna school united with the preceding pathological anatomy and founded the local method. Next appeared experimental physiology and pathology, which constituted the so-called Berlin school. Traube, who utilized Virchow's lifework in the clinic, gave to it a foundation of actual experimental pathology. This was the way whereby from medicine as a practical science the exercise of an art was developed. The chief cause for the flourishing of medicine is the laboratory that may be utilized more and more with the highest energy, but ever mindful of the fact that the chief duty of the physician is the acquisition of professional success. Else were we medically poor despite all wealth in pathological details. Hence in hospital construction scientific requirements are never alone requisite, nor should hygiene and therapy be thrust into the background. The successes in connection with tuberculosis, syphilis, diptheria, puerperal sepsis, etc., show that we are progressing. The costly technical arrangements for diagnosis and therapy are necessary for the clinic. The right utilization lies, however, in caring for the simple and universally applicable. All refinements in auxiliary media do not yet assume success. Only the well trained physician can apply them successfully. "To the sword belongs the Caliph's arm." Therefore one should never pause in the onward development of medical instruction.

Congenital Absence of the Femur.—Mummery reports a child two months of age in which the left femur was absent. The left knee appeared normal but was close to the hip. The leg below the knee was normal but was rotated outward. An *x*-ray photograph showed the diaphysis of the femur to be absent. The lower epiphysis appeared to be normal and there was a small island of cartilage just above this. The tibia and pelvis were normal. There were no other congenital defects. —*Proceedings of the Royal Society of Medicine.*

OUR LETTER FROM COPENHAGEN.

(From Our Regular Correspondent.)

TREATMENT OF TUBERCULOSIS OF THE LARYNX—NORTHERN DERMATOLOGICAL ASSOCIATION—LUPUS—LICHEN RUBER—TREATMENT OF GONORRHEA IN WOMEN.

COPENHAGEN, June 26, 1910.

At a meeting of the Medical Society of Lund (Sweden) Dr. S. A. Pfannenstill read an interesting paper on a new and apparently very efficacious method of treating tuberculosis of the larynx. The method is a new one, as it utilizes a powerful disinfectant in statu nascendi on the affected area in the following way. The patient is given sodium iodide by mouth in ordinary therapeutic quantities, and is further treated by reiterated inhalation of ozone, suitably diluted. By the reaction between sodium iodide and ozone in the diseased tissues, iodine is set free and exercises in statu nascendi its strong disinfectant powers. Dr. Pfannenstill has observed that inhalation of ozone in suitable concentrations does not inconvenience the patients in any way. If the ozone concentration is too high, coughing occurs, but no other irritation of the respiratory passages (no catarrh). As, of course, the production of iodine in the tissues varies with the proportion of ozone present in them (and in the inspiration air) it is important to increase the quantity of ozone to that very point, where coughing begins. This point is reached later as the treatment proceeds, because the mucous membrane acquires a sort of tolerance toward ozone. The ozone producing apparatus making considerable noise, it is impossible to apply treatment during the patient's sleep, which otherwise would present great advantages. But an installation of the apparatus far away from the wards might probably solve this question.

The clinical researches of Dr. Pfannenstill go to show that neither sodium iodide nor ozone has any effect on the tuberculous affections in question, when given alone. Only when used together, they bring about the desired effect. According to his experience, only tuberculous (not syphilitic) ulcerations are healed in this way. In cases of deeply seated tuberculous infiltration, or where the tuberculous deposits are covered by an intact epithelium he does not expect any improvement, as the ozone presumably penetrates only a very short distance into the mucous membrane. But one of Dr. Pfannenstill's cases shows also that an operation by laying open the affected tissue may facilitate the cure by the combined sodium iodide and ozone treatment.

Dr. Pfannenstill's clinical material consists so far of four cases of what seemed rather desperate ulcerating tuberculosis of the larynx, hypopharynx, rhinopharynx, and nose cavity. In all the cases the ulcerations healed up with astonishing rapidity. A case of lupus has been successfully treated on the same principle (sodium iodide by mouth and permanent fermentation with hydrogen peroxide). On the other hand the method has failed in two cases of bone tuberculosis, apparently on account of the circumstance, that the ozone could not be brought in sufficient contact with the ulcerations.

The first congress of the Northern Dermatological Association met recently in Copenhagen. Of the many important contributions some few are mentioned here. Dr. H. Forschhammer's clinical observations on lupus vulgaris with particular regard to prognosis and therapy were based on the whole clinical material of the Copenhagen Finsen-Institute in the period of 1896-1906. The disease begins most often (81 per cent of the cases) in the face and during the first two to four years only the skin is affected and no destruction is to be feared, as in this period there is a fair probability of recovery without disfiguring scars. The Finsen light treatment ought to be preferred, as it brings about a cure in 75 per cent. of the cases with cosmetic results far surpassing those of any other method; while it is highly dangerous to experiment with uncertain methods of treatment in this early stage of the disease. In later periods other therapeutic measures may be recurred to (for instance, excision). Some cases prove refractory to any treatment.

Dr. H. Boas had investigated the relation of prurigo Hebræ to tuberculosis by injection of tuberculine. Only in one-half of the cases a reaction was observed, so that no connection between these two diseases is necessarily to be presumed.

Dr. C. Rasch contributed clinical and therapeutic researches on lichen ruber. Arsenic, the most frequently employed therapeutic agent, was not always

tolerated. For such cases far better effect was seen from valerian preparations or from mixtures of acetphenetidin, antipyrine and aspirine. The local treatment may also sometimes make the affection worse. In these cases a paste of zinc oxide or one of the well-known old emulsions of zinc oxide, diluted solution of lead subacetate and lime water may give satisfaction. Drs. Afzelius and Marcus (Stockholm) had also seen cases cured without the use of arsenic. In two cases exposure to sunlight had sufficed.

Dr. Alma Sundquist (Stockholm) read a paper on the treatment of gonorrhoea in women. Local treatment was to be preferred to the exclusively hygienic-dietetic treatment. As a new therapeutic agent she recommended hydrochloric acid in one-half per cent. dilution, both for instillation into the cervical canal with Braun's syringe and for local treatment of the urethra four to five times daily. The results had proved somewhat better than those derived from silver preparations, and the treatment is a very cheap one.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 14, 1910.

Bilious Attacks in Children.—Philip S. Potter calls attention to the danger that lurks in a vague term like this. In every "bilious attack" the possibility of appendicitis should be foremost. The classical symptoms of appendicitis are often very slight in children and in all cases having a history of bilious attack a careful examination of the child's abdomen should be made, if possible, at the time of the attack. Recurrent vomiting and recurrent pyrexia are conditions that may be overlooked; the former yields readily to large doses of soda bicarbonate, and the latter condition is remedied by the exclusion of sugars and starches and the administration of calomel and arsenic. Both of these conditions are most common in nervous children. Beginning meningitis, migraine and renal vomiting have been mistakenly diagnosed as bilious attacks. Even otitis media has been known to produce symptoms commonly observed in a bilious attack. The most common and least significant of the so-called bilious attacks are those due to gastric indigestion or intestinal toxemia. While the term bilious attack may mean the most innocent of digestive upsets, the diagnosis must be carefully sifted and a thorough physical and clinical examination made and other possibilities excluded.

The Etiology of Common Colds.—A. Coolidge expresses himself as being in sympathy with the assumption that this term means an acute bacterial infection of the mucous membrane of the upper respiratory tract. Among the acute disorders of the nasal chambers we may distinguish some as due to infection and others as arising from a local irritability and vasomotor disturbance. When we recognize this difference more definitely we may classify the latter with hay fever and its kindred, and announce that a "real cold" is a contagious disease. There is much evidence to prove that a common cold is contagious, and the community would gain much by this assumption. The writer agrees with other observers that colds have an incubation period of from two to four days; that they remain contagious for several days, and that acquired immunity is short. The objection to draughts and wet and cold, in moderation, which induces humanity to shut itself up in air tight enclosures, is often due to an unwarrantable fear of "catching" just those diseases which are communicated by sneezing, coughing, and poor ventilation. The author discussed, in addition to that form of cold which he designates as a "common cold," other types which, although having some symptoms in common, differ enough to make it probable that, while infectious, they are due to some other organism.

New York Medical Journal, July 16, 1910.

Some Surgical Aspects of Gastric Ulcer.—Parker Syms considers some of the dangers, immediate and remote, of gastric ulcer and the reasons why they should be promptly cured. No case of chronic indigestion should be allowed to pursue an uninterrupted course. If a cure is not brought about by hygienic and dietetic means within three or four weeks, the case should be considered a surgical one. The writer makes a plea for exploratory laparotomy in these cases. If properly done, it will result in no harm, and if often resorted to it will save countless lives. Modern methods have reduced the mortality to a a point where operation should no longer be dreaded. Chronic ulcer of the stomach and duodenum results in a mortality that we cannot estimate, but which is known to be over 50 per cent. Incurable gastric symptoms constitute a good and sufficient reason for operating. We should not wait to be sure that there is a perforation or hemorrhage, but should give the patient the benefit of the doubt by an early exploration. He agrees with Dr. Rodman in his advocacy of a more radical procedure than that of gastroenterostomy. In that way only can one be sure of preventing recurrent hemorrhage; in that way only could one be sure of avoiding post-operative perforation and of avoiding the implantation of cancer on an ulcer's cicatrix.

The Value of Test Meals.—J. Russell Verbrycke thinks that there are many who either undervalue the test meal or are prejudiced against it. One can by painstaking history and careful physical examination make a diagnosis in a number of the anatomical diseases of the stomach, but one is aided and has his opinions confirmed from examination of a test meal. One can by this means arrive at the extent of the functional changes which are coincident with the anatomical disease. In the purely functional changes one can only obtain a definite idea as to the degree of abnormality by means of the test meal. The use of the stomach tube in addition to recovering material for examination, can tell if there is any organic stricture or spasm of the lower end of the esophagus or cardia. It can also determine the length of time food remains in the stomach, the condition of motility, the presence or absence of pyloric obstruction, and whether the patient eats hastily, without proper mastication. There are certain points the forgetfulness of which may lead to skepticism in regard to the value of the test meal. Conclusions cannot always be based on the results of one meal. A uniform meal should be employed. One should recover all that can easily be obtained in order to form a relative idea of the amount of secretion and to avoid getting a small amount from the cardia which may differ from the rest of the contents. Microscopical and macroscopical, as well as chemical, examination should be made. The author gives a summary of the findings and their importance in the various stomach affections and, in conclusion, makes a plea for more frequent test meals in the diagnosis of stomach affections; believing that by giving due consideration to and properly correlating all the findings we are arriving at greater exactness, eliminating much of haphazard diagnosis and therapy, and are putting the subject on a much more rational basis.

Journal of the American Medical Association, July 16, 1910.

Anomalous Scarlet Fever.—Harold Newton Cole reports three epidemics, in all, 32 cases, of what he supposes is anomalous scarlet fever, which occurred at the Lakeside Hospital, in Cleveland. In each of these epidemics the disease might have passed unrecognized had not one or more typical cases occurred which acted as a diagnostic control. These epidemics were characterized by the mildness of the attack and the benign course of the disease, together with suppression or complete absence of the exanthem, as well as of some other of the important symptoms. The temperature in these cases varied from normal to 105°, but in general it ranged from 100° to 102° F. In only two cases was there absence of all the signs of nephritis. Practically every case had severe angina. The changes noted in the blood were a marked increase in the number of leucocytes in a few cases, and in a number of instances the differential blood count showed a high percentage of eosinophiles. From these epidemics, as well as others cited, it appears that the toxin varies in different outbreaks. It does not appear that mild infections beget malignant strains, or the reverse. From the fact that the tonsils are involved at a very early stage, and from the constancy with which this symptom has been noted, it would seem that the infecting agent gains access through these glands, as claimed by Dawson and Lemoine. It seems unwise with our imperfect knowledge concerning the etiology of scarlet fever to regard these aberrant forms, which point strongly to some aberration of the exciting cause, as distinct affections.

Lutein Extract in the Treatment of Decreased Menstruation and the Premature Menopause.—Basing his experiments on the hypothesis that even if the corpus luteum of the ovary is not the cause or stimulus of menstruation, at least this internal secretion of lutein has a distinct influence on the production of menstruation, Ellice McDonald has been experimenting clinically for the past five years with dessicated extract of corpora lutea of the ovary of cows. He has treated in all twenty cases. Ten of these were of scanty menstruation or approaching premature menopause, seven of whom were improved, and three were not benefited, being well established cases

with marked nervous symptoms. Amongst the ten cases of surgical menopause, one patient was made distinctly worse, five were not improved, and four reported some improvement. The results of this study seemed to indicate that the control of the surgical menopause need not be sought in the corpora lutea. Its value is in cases where the uterus and ovaries or the uterus alone are retained. Particularly is it valuable in the treatment of scanty menstruation and the premature menopause. Lutein extract should be accompanied in suitable cases by dilatation of the uterus, with the use of the stem pessary following operation. The administration of lutein is indicated after operations on pregnant women in whom miscarriage is feared. This is particularly true during the early weeks of pregnancy, as it has been shown experimentally that the corpus luteum has a definite effect under such circumstances.

The Relation of Stuttering to Amusia.—E. Bosworth McCready is of the opinion that there has never been a satisfactory explanation of stuttering. To call it a neurosis does not explain why certain individuals under the influence of fright, imitation, acute disease or nasopharyngeal irritation begin to stutter, while others equally neurotic and exposed to the same influences do not. After discussing the etiology and methods of treatment he concludes that, while incapable of proof, it is reasonable to suppose: (1) That the defective use of the muscles of inspiration, expiration, and of the lips, tongue, and throat, resulting in stuttering, is the "result of imperfect coordination, caused by disconnected and erratic discharges from the cortex." (2) That this incoordination is between the nervous mechanism controlling the acts of vocalization and articulation and the centers having for their function the appreciation and expression of melody and harmony, and is due to a biologic variation in such a center or its commissures. (3) That the cure of stuttering is only accomplished by a process of compensation brought about by the education of cells previously nonfunctionating, and by forcing the opposite hemisphere to supply a center similar to that which is imperfectly developed. To this end the reversal of dexterity would seem to be a reasonable procedure.

The Treatment of Furunculosis.—John T. Bowen does not believe that early incision shortens the duration of this affection; nor does he recommend poulticing, as it is contrary to aseptic principles. While most brilliant results have been achieved in some cases from the vaccine method, there are a certain number of cases that do not respond to this treatment, and for these he recommends a method of treatment whose principle is simply to keep the skin as far as possible sterile. The patient is directed to wash the entire body with soap and warm water every night and morning, and then after the surface of the body is dried it is bathed with a saturated solution of boracic acid in water. The skin is allowed to dry without wiping and the individual furuncles are dressed with an ointment composed of: boracic acid, 4 grains; precipitated sulphur, 4 grains, and carbolized petroleum, 32 grains. Incision is resorted to only after the lesions have become very painful and mature. All clothing that comes in contact with the skin should be changed daily, and everything done on general therapeutic principles to promote the well-being of the patient. This method rarely fails when carried out with care and patience.

Syphilis in Insanity as Determined by the Wassermann Reaction.—C. B. Ensor has tested 262 male patients from Mount Hope Retreat by the Wassermann method, and obtained a positive reaction in 22 per cent. of the total male population. Of the 262 patients, a history of syphilis was given in only 3 per cent. of the total, and only 14 per cent. of those showing the positive reaction admitted having had syphilis. Of the positive cases 69 per cent. have been in the institution one year or under, 12 per cent. have been there two years, and 19 per cent. have been there three years and over. Of 21 patients from other sources 16 were paretics, with a positive reaction in all. Of 27 cases of paresis collected from all sources, 96 per cent. gave a positive reaction. Of 7 cases of tabes 83 per cent. were positive, and of 5 cases of cerebral syphilis, 4 were positive; in the negative case the patient had been receiving mercurial injections for six months.

The Lancet, July 9, 1910.

Submucous Resection of the Nasal Septum.—H. Bell Tawse, after alluding to the structure of the nasal septum and describing the Killian operation, which he used with a few modifications, gives a review of 120 cases upon whom he had operated. In this series of cases he used only a local anesthetic, preferably a mixture of equal parts of 20 per cent. cocaine hydrochloride and 1 in 1000 adrenalin chloride. Ether should never be used because it congests the mucous membrane and increases hemorrhage. As a rule, the operation occupied about 25 minutes. Children under 12 years of age are not, according to Killian, fit subjects for this operation, but he had done it in three cases, aged respectively 8, 10, and 12 years. The others ranged in age from 15 to 55. In only 5 per cent. of the cases was the deviation purely cartilaginous; the remaining 114 cases were both cartilaginous and bony. Twelve cases had a traumatic origin; the others were apparently developmental, though it might be possible that traumatism had a share in the production of the deformity. In 75 per cent. there was marked enlargement of the maxillary crest. Disease of the middle turbinate was noted in 51 patients. In 20 there was active sinus suppuration. In 25 cases there were polypi necessitating ethmoidal curetting. Unilateral atrophic rhinitis, a rather rare condition, was present in three individuals. In 18 cases there was complete collapse of the alæ nasi. Sneezing and rhinorrhea were the main symptoms in 4 cases, while 2 had asthma, 5 chronic dry rhinitis, 3 adhesions of the basal spur, 15 middle-ear catarrh and deafness, and 80 per cent. complained of supraorbital and frontal headache. Nine out of the 120 had perforation after the operation, five occurring in the first 20 cases. Out of the last 100 cases there were but two perforations, and these were very difficult cases.

The Examination of Feces in Medical Practice.—Oscar Kraus says that in the treatment of gastric and intestinal diseases it is frequently very difficult to prescribe for any given patient a diet which is adapted to the activity of his digestion and assimilation, and in which each disturbance of function in the various portions of the digestive tract is taken into account. The examination of the gastric secretion can only give information in regard to digestive activity which takes place in the stomach, and it is more difficult to secure the cooperation of the patient in securing samples of gastric secretion than it is in obtaining feces. The aim of the examination is threefold, namely, to find how the patient digests the ingredients of his normal diet, what class of foodstuffs he might add, and what he ought to avoid. The methods of examination are those usually employed. A macroscopical examination is first made. The first chemical examination undertaken deals with the secretion of bile. A portion of the feces is stirred up in a concentrated aqueous solution of perchloride of mercury. Under normal condition, after some hours, all the portions containing hydrobilirubin take on a red color, while those containing bilirubin take on a green color. An indistinct reaction shows that the secretion of bile is partly or wholly inhibited. In the next place some feces are placed in a Schmidt's fermenting flask. A distinct evolution of gas taking place within twelve hours indicates that the digestion of starch has been unsatisfactory. The reaction of feces under these conditions is found to be distinctly and increasingly acid. This occurs especially in catarrhal conditions of the small intestine, which is practically the only situation where carbohydrates are digested. When gas is produced in from 24 to 48 hours it means that the albuminous substances are being split up by increased alkalinity, which indicates that there is intestinal decomposition dyspepsia. The examination of fat is limited to the determination of the proportion of split up fat to total fat. The greater the quantity of total fat, the more defective is the fat absorption. Of all the tests for blood only the aloin test has proved itself satisfactory, because it is the only one in which the presence of iron in the feces does not affect the result of the reaction. Microscopical examination permits a fairly accurate determination of the condition of the digestive activity of the stomach and small intestines. The presence of a considerable amount of connective tissue and elastic fibers indicates a defect in acidity of the gastric juice. In such cases a certain amount of coagulable proteid substances is usually found. The appearance of elastic fibers in the feces, if not associated with connective tissue and coagulated protein, must be regarded as a sign of good gastric, but poor intestinal, digestion. The absence of pancreatic enzyme can be recognized by undigested pieces of muscular tissue, in which more or less well-preserved cell nuclei are visible. If upon testing a smear of feces with a drop of Lugol's solution, a considerable amount of blue colored starch granules is seen it may be assumed that the patient's amylolysis is impaired. In testing for mucus a smear of feces is stained with a 1 per cent. solution of alizarin sulphate of sodium. The greater the distance between the situation where the mucus is formed and the anus the more weakly is the mucus stained. Cases are cited illustrating the application of these results to the regulation of the details of diet.

A Case of Extrauterine Pregnancy Occurring Twice in the Same Patient.—George A. Gordon reports this case because he thinks it is exceedingly uncommon for a woman to be the victim of an extrauterine pregnancy on two distinct occasions. The patient had been married two years when she missed a period and consulted him for what she supposed was a bilious attack. He diagnosed a ruptured tubal gestation. At operation he found the left tube was ruptured and the pelvis full of blood. The tube was found to contain a fetus of seven weeks. About three years later the same patient consulted him and he found the right tube swollen and, suspecting an extrauterine pregnancy, operated, finding a six weeks' fetus. The patient made a good recovery.

British Medical Journal, July 9, 1910.

Suprapubic Drainage of the Bladder as an Alternative to Prostatectomy and as a Relief Operation.—J. B. Pike recommends suprapubic drainage of the bladder in cases of cancer in which operation would not offer a very hopeful prognosis, or in cases in which catheterism is unsuccessful. He cites two instances as evidence of the value of this procedure. The first case was one of acute retention in which catheterism was unsuccessful and in which prostatectomy was refused. This patient has drained the bladder for upwards of five years, part of the time with a rubber tube and more recently with a silver tube. His general condition remains good, and he has led quite an active life for a septuagenarian. The second case was one of multiple papilloma above the trigone in which this measure has given great relief for many months.

The Incidence of Tuberculosis in Childhood.—Franz Hamburger and R. Monti, in making this investigation, examined only children who were suffering from acute infectious diseases, as in this way they obtained material which represented fairly accurately the real state of child life in Vienna. They found that out of 532 patients suffering from scarlatina or diphtheria 271, or about 50 per cent., reacted positively to a subcutaneous tuberculin injection of 1 mg. From their statistics they summarize as follows: (1) The majority of persons become infected by tuberculosis in childhood. (2) The frequency of tuberculous infection increases from year to year, while tuberculous morbidity, that is, the frequency of manifest tuberculous disease, decreases from year to year. (3) Tuberculosis is very commonly latent, producing no symptoms. This is especially so if the infection dates from the third or fourth year. (4) The prognosis of tuberculosis in childhood becomes more favorable the older the person is at the time of the first infection.

On the Presence of Sugar in Healthy Urine as a Source of the Osazone Reaction.—F. W. Pavy and H. W. Bywaters describe the method of procedure by which they demonstrate that the amount of sugar present in normal urine is sufficiently large to permit of osazone crystals being obtained by direct treatment with phenylhydrazine. They find that the quantity of sugar present in normal urine, even though it does not give a reaction with Fehling's solution on account of the inhibiting effect of certain of its constituents, is really considerable in quantity, amounting to 2.5 or more per 1000. It is to be looked upon as nothing more than a natural occurrence that osazone crystals should be obtained from normal urine, and it all depends upon incidental circumstances whether they are obtained or not. The urines of horses, cats, and rabbits have been subjected to experimental treatment, and in most all instances have been found to yield typical osazone crystals.

Injury of the Ear by a Hatpin.—Alfred Mann reports the case of a patient, who in putting on her hat accidentally ran the pin into her ear. No perforation of the tympanic membrane could be found, but close to the drum the floor of the meatus showed a scratch. Under careful antiseptic dressing the ear healed without discharge, but a considerable degree of deafness and tinnitus still remain. There was no doubt but that the patient had partially dislocated the stapes from its vestibular attachment, or at least altered its position.

Calcium Chloride in Rhinorrhea.—Richard Lake finds that with scarcely an exception rhinorrhea has responded to calcium chloride. He gives 30 to 40 grains a day for two weeks. If this objectionable symptom recurs it will again yield to this treatment. He does not attempt to explain the pathology but thinks that perhaps the amount of chloride in the blood may yield a hint as to the causative factor. The salt may possibly be of use in spasmodic sneezing, hay fever, or asthma.

Berliner klinische Wochenschrift, June 27, 1910.

Sudden Blindness from Organic Disease.—Uhthoff describes two cases of bilateral sudden blindness in elderly people in which all the ordinary causes of this phenomenon, such as hysteria, intoxications, traumatism, acute hemorrhage, etc., could be excluded. Despite the suddenness of the attacks the ophthalmoscope showed optic atrophy, following neuritis. In one patient the diagnosis, made by exclusion, was rupture of a small aneurysm with escape of blood into the sheath of the opticus. There was no blood found by lumbar puncture, but some weeks had elapsed when the test was made. In the second case it was also assumed that an intracranial lesion of the opticus was responsible, most probably an aneurism, but possibly a hypophysis tumor. The patient improved considerably while taking iodides.

Tuberculin Treatment of Renal Tuberculosis.—Wildbolz emphasizes the radical and severe character of nephrectomy in unilateral tuberculosis of the kidney, and believes that certain cases at least may be brought to arrest by tuberculin injections. There is of course a possible fallacy involved, because spontaneous improvement is by no means unique. Two cases cited by the author were treated some years ago, and in one of them there has been arrest of the disease for nine years. He gives another series of cases in which, after prolonged tuberculin treatment, the patients had to be nephrectomized. It does not appear that in this series the tuberculin treatment stayed the progress of the renal lesions. These opposite types of findings are probably explained by the character of the process in each series. The recovered cases are doubtless of the same type as those which undergo spontaneous cure—small, beginning, localized, and eventually encapsulated. The other cases are of the destructive type, with tendency to local infection and general intoxication. But while the natural forces are in some cases sufficient for an arrest of the process, there seems no reason to doubt that the action of tuberculin may be antagonistic to local infection up to a certain point, as well as antagonistic to the toxemia. Improvement in general condition was noted under the tuberculin treatment. The author has been and is a prolific nephrectomist, but this does not deter him from advocating a medical resource as a competitive procedure in a surgical disease.

Cystic Kidneys and Renal Cysts.—According to Renner, modern opinion is favoring the view of the ultimate identity of these conditions. Originally secondary cyst formation was regarded as a sort of incidental termination of diverse inflammatory affections, while primary cyst formations naturally came under the head of neoplasia. Another distinction came to light in the contrast between inevitable or congenital cysts, and those purely acquired in later life. The former were explained on developmental grounds alone, while the latter were alleged to be due inevitably to nephritis. The subject, historically considered, is so confusing that the enumeration of facts and theories seems to render any kind of consensus of opinion out of the question. It can only be maintained that the more we study the individual case the more we become convinced that conditions clinically opposite show a close pathological resemblance. One of the more common text-book differentiations makes of cystic kidneys a polycystic degeneration; while renal cysts secondary to inflammatory disturbances and incidental to obstruction in the lower urinary passages are stated to be large and single. This distinction seems at first sight to be reasonable throughout; and further sheds light on the essential differences between neoplastic and inflammatory cysts, and between the congenital and acquired types. The author, however, cites a number of cases seeking to show that such a distinction is not tenable. Polycystic kidneys in adult individuals requiring extirpation seem to show a tendency to fusion into a single cyst. It does not appear that these cases could have had other than an embryonal origin not manifested until senile decay. It is also claimed that 50 per cent. of newly born infants show minute cysts throughout the kindneys. We are, therefore, in a measure forced to conclude that cystic kidneys, in the form of small multiple cysts, are one of the more common congenital defects; that according to various accidental circumstances these cysts may either enlarge individually without coalescence, and constitute polycystic degeneration; or that they may coalesce to form a single large cystic cavity. It also appears that in old age congenital cystic anomalies latent for a lifelong period may assert themselves. It does not appear that a purely pressure atrophy of the kidney, such as results in hydronephrosis, and which thereby replaces the kidney by a sac of fluid, is meant to be included under cystic disease proper. The author alludes casually to such kidneys without much comment.

Habitual Torsion of the Colon.—Augsbach, a Russian practitioner, concludes that volvulus of the colon is an affection which tends eminently to recurrence. Hence he thinks it justifiable, unless the indications for resection are unmistakable, to perform a colopexy. He would not resort to such procedures until the tendency to relapse was very marked. In a case cited the patient had no less than five or six attacks of colonic ileus annually. Statistics show that the sigmoid flexure is the chief seat of the volvulus—in fact, torsion of the sigmoid and small intestine causes in the neighborhood of half of all cases of volvulus. The rest of the colon is much less commonly involved. The author's case, however, involved the transverse colon only.

Münchener medizinische Wochenschrift, June 21 and 28, 1910.

Paths of Infection and Course of Pneumococcus Meningitis.—Grober, of the Public Hospitals, Essen, says of the pneumococcus that "both the blood and lymph vessels are open to it." Much attention has been given by pathologists to the spreading of local pneumococcic infections along the lymph channels—as when a pneumonia gives rise to pleurisy and pericarditis. In theory at least, propagation along lymph channels and spaces, including the great serous cavities, might result indefinitely. Another train of symptoms may be imputed to bacteriemia, and still another to toxemia alone. It is therefore a matter of great difficulty, when a particular structure like the meninges is attacked, to determine the precise rationale of the complication. It is true that as yet no one has demonstrated the possibility of direct lymphatic transmission from pleura to subdural space; but some autopsy cases are better explained by such transmission than by any other. Hematogenous transmission may in theory occur so readily that we are satisfied to explain many cases of meningitis in this way, despite the absence of proof. That bacteria may be propagated directly from the tonsils to the great serous cavities, including the subdural space, is a claim much less speculative in character—in fact its accuracy is hardly open to question. Another means of access of the pneumococcus—as it occurs normally in the throat and nose—to the subdural space is furnished only in connection with fracture of the base of the skull (cases of this genesis being sufficiently well known to clinicians and pathologists). Pneumococcus meningitis, however engendered, is quite rare as an independent, isolated affection. Naturally we were not in position to recognize it during life until the introduction of diagnostic lumbar puncture. All are agreed as to its fatal character, whatever its association. Survival, in cases with diagnosis made bacteriologically *intra vitam*, is practically unknown. Cases of pneumonia occur in which with evidences of meningeal irritation (meningismus) we find no bacteria in the cerebrospinal fluid. Such complications are best explained, perhaps, by toxemia of hematogenous origin; but recoveries may be due to mild cases of lymphatic origin, in which repeated examinations of the cerebrospinal fluid would have revealed bacteria.

Tuberculosis and Lactation.—Deutsch, of Frankfurt, a/M, writes an unpretentious but quite exhaustive monographic article on this subject, recording extensive personal experience and appending a number of references to work of his predecessors. The question, "Shall a tuberculous mother nurse her infant?" naturally enters into the general campaign against tuberculosis; but it loses a little force from the fact that tuberculous women not only do not conceive in the ratio of healthy women, but also have a natural tendency to abort. Nevertheless cases of childbirth in tuberculous women are not only plentiful enough, but not a few infants so conceived and born are vigorous enough to survive the ordinary risks of infancy. The problem thus becomes highly complicated. We deal only with actual births, not with the advisability of marriage and gestation. For a consumptive mother to nurse an infant is in itself a severe drain; but tuberculosis is a disease which, however severe it may be in its pulmonary symptoms, may still respect the organism at large. Certain individuals with the slow, fibroid type of pulmonary infection are able to discharge the ordinary duties of life for many years—if they are so situated as to be able to favor themselves. Mothers who come under this head may suffer for years from hemoptyses and various kinds of invalidism imposed by tuberculosis; and during this period may give birth to seemingly healthy children, who remain healthy for years. The author believes that women actually known to be tuberculous should never nurse their infants; those who are merely suspected of tuberculosis may nurse their infants under medical supervision until a clearer diagnosis is made. The nursing of an infant by a known tuberculous mother constitutes a double menace, prejudicial both to the child and the adult. In the warfare against tuberculosis this contingency should be abolished at the start. The author does not incorporate in his conclusions any reference to the ability of a tuberculous mother to infect an infant born healthy, although he does justice to this possibility in the text of his article. But too many problems arise in this connection to be decided offhand. There is the question of direct bacillary transmission, the question of direct absorption of toxins, and finally the matter of inheritance of defective resistance to disease. The incidence of tuberculosis among short-lived folk of any kind is very large, and all pathologists know to what extent diabetics, lepers, syphilitics, and similar victims succumb at last to tuberculosis; this is true to some degree of those of neuropathic inheritance. The author describes the instance of a tuberculous mother striving to nurse her child according to theoretic requirements. The effort is enormous. The mother, besides responsibility for her own nutrition, is obliged to be answerable for every detail in the care of the child. She is up at all hours, preparing, sterilizing and what not—and the drain on her powers would appear to be out of proportion to the possible good derived by the child. In other words, what she loses the infant by no means gains.

Treatment of Placenta Previa.—Hofmeier states that the entire subject of the treatment of placenta previa has been stirred up of late by the advocacy of the cesarean section and of various equivalent intravaginal procedures. He states that during one year in Schroeder's time he was called upon to superintend 37 cases of this complication in Berlin services, and that of this number he lost but one mother, who was not under complete control, and evidently infected from gross carelessness. She died of pyemia on the 17th day. The case was intrinsically not more severe than that of many patients who recovered. The author's 36 survivors were delivered by the combined procedure of Braxton Hicks or simply left to spontaneous birth. In 19 of the 37 cases the condition was one of placenta previa totalis. This result was much better than the average then obtainable, just as it is much superior to many to-day, at least as far as the mothers are concerned. But under this treatment the child mortality is heavy. To attempt to lighten this Küstner warmly advocated metreurysis. It must be remembered, however, that the child mortality depends largely on death in utero before the case even comes to consultation. In Hofmeier's services metreurysis was never used until 1903. Before that period he depended, as already stated, on spontaneous delivery (merely rupturing the membranes) or the Braxton Hicks maneuver. In a series of 100 placenta previas since 1889 the maternal mortality was 8, but 5 of the deaths in no wise depended on the mode of delivery, as death would doubtless have occurred under any form (acute miliary tuberculosis, fulminating sepsis, eclampsia, etc). It would be important to know whether or not Cesarean section could have saved these three mothers; but the mortality is so low that it is hardly greater than in many series of miscellaneous labors. The matter of more signal interest is the child mortality with especial reference to metreurysis. In 55 labors with placenta previa before the introduction of this resource, the child mortality was 59 per cent., while in 19 labors with metreurysis, 14 infants were born alive—and some of these were premature—which means a mortality of but 26 per cent. In order to eliminate the prematures from mortality tables it is the custom in some clinics to divide labors into those before and after the thirty-second week, and by any method of delivery, the child mortality must be materially modified by this distinction. The author believes that severe surgical measures should not come into routine use in placenta previa, although they may possess a narrow field in special cases.

Pathology of the Suprarenal Bodies.—Roessle's article is concerned largely with autopsy findings, including studies on the fetus. He knows of no case of total absence of these glands, but hypoplasia is very common, and affects sometimes the cortex and sometimes the medulla. In no case has there been total defect of either part as a primary condition. Hypoplasia often accompanies the status lymphaticus. In order to get a definite idea of what total absence of suprarenal tissue means we have evidently to depend wholly on changes due to disease. We know that the adrenalin producing substance becomes completely exhausted under a variety of conditions—general narcosis and acute intoxications, and excessive muscular activity, including convulsions and tetanus. Paradoxic chloroform deaths have been explained by the fact that there was a natural defect of medullary substance. Fully as significant as hypoplasia is hypertrophy

of the suprarenals. Congenital enlargement, as seen in a few cases of dead fetus, has seemed to be associated with a hypertrophy of certain other organs, as the uterus, indicating a sort of precocious development. The gland of one side may undergo compensatory hypertrophy if the opposite one is removed or destroyed. Of great interest is a connection which seems to exist between hypertrophy of the medulla and tendency to hemorrhages; as if a state of plethora was induced by overaction of the adrenalin producing tissues. The losses of blood occur under conditions which favor such losses, but why they should occur in one patient and not in another may be bound up in part in this subject of suprarenal plethora. The author concludes with the lines of experimental work necessary to throw light on this subject.

Methods for Demonstrating Oxidizing and Reducing Substances in the Body.—Loele gives brief mention of several methods which are put forward rather for trial than as well-tested resources for diagnosis. The granules of the oxyphile cells of the leucocytes in the pulp of the spleen, those of the salivary gland epithelium, etc., have the property, in alcohol solutions of phenol, of assuming a yellowish to black hue. All oxyphile cells, however, do not possess this property. The coloring principle behaves as an acid, and the intensity of the color varies apparently with the number of hydroxyl groups. The color phenomenon is believed to be due to the action of an oxidase or oxidizing enzyme. Reduction phenomena imputed to the possible activity of a reducing enzyme or reductase are very briefly mentioned, and silver, pyrogallol, and similar reducible substances are used for demonstration.

Deutsche medizinische Wochenschrift, June 23 and 30, 1910.

Eye Symptoms in Diseases of the Frontal and Ethmoidal Sinuses.—Gutmann has collected notes of a number of different affections of the orbit and eye consecutive to empyema and mucocele of the frontal and ethmoidal sinuses. He first describes a number of cases of orbital phlegmon following frontal sinus disease; while in a second series the same accident followed empyema of the anterior ethmoidal cells. In a further series disease of the posterior ethmoidal and sphenoidal cells gave rise to pressure lesions of the optic nerve. The pressure was caused in the author's case by polypoid vegetations, which grew from the cavities in question, although in the experience of some reporters the pressure was due to retained pus. Generally speaking accurate diagnosis in such cases led to the adoption of measures for the relief of the serious condition, with spontaneous improvement in the intraorbital lesions. In a number of well-recorded cases the appearance of a central scotoma appeared to be an early symptom of an extension of suppuration from the sphenoidal sinus to the eyeball. Birch-Hirschfeld attributed the scotoma to the direct action of toxins formed in the course of suppuration. Cases of intraorbital disease from sinus empyema have multiplied rapidly since 1895. Attempts have been made to locate the source of the sinus pus from the character of the orbital phlegmon. Thus pus escaping from the sphenoidal sinus is believed to cause edema of the lower lid, with marked conjunctivitis—including chemosis—confined largely to the lower half of the membrane. If the pus comes from the ethmoidal cells, it collects at the inner canthus, displacing the bulbus oculi outward and causing crossed double vision with no difference in the height of objects. There are naturally exceptions to any general rules of this sort which may be set up. It is also true that radical treatment of the sinuses, by establishing free drainage, does not always cause radical cure of the orbital phlegmons, which have been known to form anew.

Coincidence of Diabetes Mellitus and Asthenia Congenita.—As is well known, Stiller described a condition known as asthenia congenita, which he claims to be responsible for certain paradoxic conditions, like the development of diabetes in boys and young men. A leading symptom of this asthenic state is idopathic atony of the stomach. These subjects are predisposed from the start to a series of destructive and fatal diseases—diabetes, nephritis, arteriosclerosis, etc. Graul of Bad Neuenahr tested a series of 170 cases of diabetes mellitus for evidences of Stiller's congenital asthenia, and found the latter present in so few cases as to appear to represent a mere coincidence. The habitus asthenicus is manifested by atony of the stomach, enteroptosis, indigestion, neurasthenia, chlorotic tendencies. The very few patients who seemed to present this habitus showed some further predisposition to diabetes, such as alimentary glycosuria (indicating an intolerance toward carbohydrates), or diabetes in the ascendants. Whatever may be said of the existence or non-existence of Stiller's asthenic constitution and its tendency to invite the early appearance of degenerative and fatal diseases, it does not appear as if diabetes should be reckoned among this number.

Inflammatory Pseudocarcinoma of the Appendix.—Milner speaks of the confusion attendant upon a clinical diagnosis of inflammation with a microscopic diagnosis of cancer or sarcoma. This has often led to unnecessary ablation of organs. The subject is a trite one and has influenced more than one surgeon to abandon the microscopic test and trust to his clinical resources. In many cases, naturally, microscopic diagnosis is made only after extirpation, with the resulting fear of recurrence. Many appendices, the seat of presumable inflammation, show after extirpation *in vivo* or on autopsy histological characteristics of malignant disease. In approximately 1 per cent. of all removed appendices small nodules of a malignant tumor formation seem to be present. One author from independent study uses the remark that "1 per cent. of appendicitis is cancerous." The first inference would be that a malignant process sets up appendicitis and that timely removal of the appendix prevents extension of the disease. No reference is intended here to frank specimens of intestinal cancer which chance to develop in the appendix. The author fully realizes that these microscopic nodules of seemingly malignant epithelial tissue are really inflammatory. The average age (about 26 years) at which they occur is much too low for cancer. The clinical course, so far as we know, is wholly benign. The simulation of cancer is due apparently to proliferation of the parenchyma cells and endothelia of the lymph spaces. No recurrence or metastases of such microscopic cancers are on record. In a word, the lesions represent pure microscopic malignancy without a single supporting element derived from other sources.

Noguchi's Serodiagnosis of Syphilis.—Dr. Sleeswijk of the Brussels Pasteur Institute concludes that with syphilis known to exist Noguchi's test reveals nothing which cannot be told by Wassermann's original method. Under certain circumstances, which include fever, Noguchi's system causes nonspecific inhibitions, not in evidence when the Wassermann test is used. Hence the Noguchi test, so far from simplifying or improving its prototype, must be regarded rather as a source of confusion and error.

Anallergic Sera.—Ascoli of Milan writes in the interest of preventing serum disease. An allergic serum is naturally one which produces supersensitiveness, anaphylaxis, to serum injections, so that an anallergic serum is one which does not entail such disadvantages. The author appears to believe that sera should be tested on the healthy subjects, in order to eliminate makes that are toxic to all alike. In the case of one who has already had an injection, very small quantities should at first be used in second injections. In the case of a serum of proved value, like diphtheria antitoxin, many attempts have been made to profit by some animal other than the horse, especially in second cases. The supersensibility to horse serum is naturally removed by using serum from another source, especially from an animal not naturally sensitized by horse serum, or by one artificially immunized against horse serum. Since children, especially in asylums, etc., may have to be subjected repeatedly to immunizing or therapeutic injections, the problem of allergy is of vital significance. The author has tested as many herbivorous animals as possible, for he even mentions camels among the list. His anallergic serum, which after many disappointments seemed to answer the requirements, is somewhat obscurely hinted at, but the mode of preparation appears to be along recognized channels, and the work of Rosenau and Anderson is quoted in this connection. A study of the article does not inform us as to the precise technique of preparing the anallergic serum, and we are left to conclude that the latter, with laboratory secrets preserved, will enter the commercial field. We get the impression that the ram gradually supplanted the horse as a source of the serum, although the first results were not encouraging.

New Etiotogical and Pathological Conception of Icterus Neonatorum.—Enrico Munsi believes that the icterus of the new-born infant is due to a congenital insufficiency of the cells of the liver, which is, at birth, in a state of incomplete development. This causes a hyperproduction of bile by the liver cells. The child is born icteric or develops icterus soon after birth, and the condition is more frequent in the premature than in the full-term infant, and in the underweight infant. Iodophilia, glycosuria, and levulosuria are present often in these cases, showing insufficiency of the lufatic cells. There is distension of the gall bladder, and increase of secretion of bile, such as is present in the last months of intrauterine life.—*Revista di Clinica Pediatrica.*

Book Reviews.

Hypnotism and Treatment by Suggestion. By J. Milne Bramwell, M.B., C.M., Author of Hypnotism: Its History, Practice and Theory," Etc. New York: Funk & Wagnalls Company, 1910.

The author of this little book states in his preface that he has attempted to deal fully with practical points, especially causes which influence suggestibility, methods of employing suggestion, and the class of cases suitable for this form of treatment. By the term "hypnotism" he means, he says, that there has been induced by "suggestion" a condition of increased suggestibility, a condition (differing widely of course from natural sleep) in which various phenomena—surgical, medical, and experimental—have resulted from the suggestions made to the patient while he was in this condition of increased suggestibility. The author has devoted himself entirely to treatment by suggestion since 1892. The book is based on a varied and practical experience and is both interesting and convincing. It is filled with illustrative cases. As England was really the birthplace of hypnotism, we welcome a new book on the subject by one of her sons.

According to Maria. By Mr. John Lane. New York: John Lane Company, 1910.

If we are not Marias ourselves, we most of us number one among our friends or relatives, and this particular specimen of her type is certainly made entertaining enough as the gospel according to her is unfolded. It is a great pity that the genuine Marias of this world are not equipped with a little sense of humor, in which case this book might be handed round as a specific for their complaint, that of arrant and benighted mammon-worship.

Traité Pratique d'Électricité Médicale, Electrothérapie, Radiothérapie, Radiumthérapie. Par le Docteur J. Larat, Chef du Service d'Électrothérapie de la Clinique des Maladies Infantiles (Hôpital des Enfants Malades); Expert en Electricité Médicale près le Tribunal de la Seine. Troisième Édition. Avec 194 figures dans le texte. Paris: Vigot Freres, Éditeurs, 1910.

This third edition as compared to the first is almost a new book. It is truly a practical treatise on medical electricity and it is also written in a broad and eminently suggestive spirit. The plan of the book is the usual one. Technique and apparatus, electrodiagnosis and treatment are described and a very useful and interesting chapter on electrophysiology illustrates the action of various currents on muscle and nerve. The author forecasts future uses of electricity, *e.g.* the use of high frequency currents in infectious diseases, the possible advances in electrobiology, work upon colloidal substances in the organism, etc. Radium and ionization are considered but briefly.

Anwendungsformen und Wirkungsweise der Hydrotherapie bei den Verdauungs und Stoffwechselkrankheiten. Von Ernst Tobias, Berlin. Halle A. S. Carl Marbold Verlagsbuchhandlung, 1910.

As its title indicates, this brochure of fifty pages is devoted to the indications for and methods of application of hydrotherapy in disorders of digestion and nutrition. The ground is well covered and it will be found useful by all interested in the subject.

Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. By Prof. Carl Von Noorden. Part VIII, Inanition and Fattening Cures. Part IX, Technique of Reduction Cures and Gout. Authorized American edition. Edited and translated under the supervision of Alfred C. Crofton, M.D., Chicago, Ill. New York: E. B. Treat & Company, 1910.

The preceding volumes of this series of monographs dealing with metabolic and nutritional disorders have become deservedly popular, for they are admirably clear and concise expositions of subjects in which Von Noorden and his pupils have done exceedingly important clinical and experimental work. The present additions to the set are of unusual interest, and cover a field which has been urgently in need of classification. The treatment of obesity and undernutrition has been too largely a matter of empiricism and rule of thumb, whereas, excepting perhaps diabetes, in no other metabolic disorders is it so essential that the physician be able to think in calories and carry out his dietary regulations accordingly. Enough experimental work has been done to establish the technique of treatment in definite numerical principles and these little volumes form very satisfactory working guides. The chapters on gout, especially as regards the determination of the purin tolerance are equally valuable, and it is no exaggeration to say that the books should be in the hands of every practitioner who is interested in keeping up to the times. A little more attention to the proofreading and a great deal more to the English used in the translation would have contributed much to the comfort of the reader. An error of some importance is found in the table on page 47 of volume VIII, in which the caloric value of 100 g. of ham is given as 18 calories instead of 178, as it is in the German original.

Modern Problems in Psychiatry. By Ernesto Lugaro, Professor Extraordinary of Neuropathology and Psychiatry in the University of Modena. Translated by David Orr, M.D., and R. G. Rows, M.D., with a foreword by T. S. Clouston, M.D., LL.D. Manchester: At the University Press, 1909.

A true knowledge of mental diseases implies some intimacy with the many scientific problems of life. The effort to attain such a knowledge is well exemplified in the many-sided activities of the modern student of psychiatry. The latter will be guided and assisted in his arduous task by a careful study of Professor Lugaro's book, which is a recent addition to an important series of works on biological and other scientific subjects appearing in Italy within the past few years. Excellently translated, this work treats of the subject of insanity from all sides, the practical, social and scientific. It goes behind simple manifestations of insanity and seeks to discover their cerebral mechanism. To do this, the author treats of the mechanism of the normal brain in its anatomical, physiological and psychological aspects, and then discusses in what ways this may be altered, and the general relations existing between consciousness and organic phenomena, the relations between consciousness and the objective world. The real morbid process going on the psychic organ and in other organs is sought before the external cause. The division of the book is as follows: First is a general introduction in which is discussed the evolution of psychiatry as a science. Next follows psychological problems and the application of psychology in the analysis of the mental state of the insane. Then are described in order, anatomical problems, problems in pathogenesis, etiological, nosological and practical problems and conclusive remarks. Treatment of the insane, asylum administration, prophylaxis, and the relations of crime and insanity are among the practical problems interestingly discussed.

Neurasthénie et Névroses, leur Guérison Définitive en Cure Libre. Par Dr. Paul-Émile Lévy, Ancien Interne des Hôpitaux de Paris. Deuxième Édition. Paris: Félix Alcan, Éditeur, 1910.

The first edition of this book appeared last year. The present edition seems to be a reprint without revision or addition. The author has become known to Americans through his "l'Éducation Rationelle de la Volonté, son Emploi Thérapeutique," a book which has passed already through its seventh edition. Those who are unwilling to accept the methods of Dubois and others holding similar ideas to his in respect to treatment, may find in "Neurasthénie et Néuroses" moral and reeducatory methods of treatment for neurasthenia, hysteria, and certain other nervous conditions which will appeal to him.

Manual of Surgery. By Alexis Thomson, F.R.C.S. Ed.; Professor of Surgery, University of Edinburgh; Surgeon, Edinburgh Royal Infirmary; and Alexander Miles, F.R.C.S., Ed. Surgeon, Edinburgh Royal Infirmary; Surgeon to Leith Hospital. Volume I: General Surgery; with 339 illustrations. Volume II: Regional Surgery; with 227 illustrations. Third Edition; revised and enlarged. Edinburgh, Glasgow, and London: Henry Frowde, and Hodder & Stoughton, 1909.

This is one of the best known of the shorter modern works on surgery. Although published in two volumes, for the convenience of the reader, it really corresponds to the one-volume manuals used by students. The characteristics of this work are: The curtailment or omission of all theoretical or debatable matter; the description of pathological processes only in so far as they bear directly on diagnosis and treatment; the inclusion of a brief résumé of the surgical anatomy of the various regions and tissues concerned; and the handy size of the volumes, which enables the reader to hold the volume in his hand while perusing page after page. Much of the book has been rewritten, and the new material includes: Bier's treatment of inflammation and infective conditions, serum and vaccine therapy, and short descriptions of Schlatter's disease, Madelung's deformity, and the snapping hip. The chapter on the surgery of the peripheral nerves is practically new. The work is well printed, and will appeal to the busy practitioner who needs a book on surgery which is authoritative, up to date, and of moderate size.

Lehrbuch der Nervenkrankheiten. Von G. Aschaffenburg, Köln; H. Curschmann, Mainz; R. Finkelnburg, Bonn; R. Gaupp, Tübingen; C. Hirsch, Gottingen; Fr. Jamin, Erlangen; J. Ibrahim, München; Fedor Krause, Berlin; M. Lewandowsky, Berlin; H. Liepmann, Berlin; L. R. Müller, Augsburg; Fr. Pineles, Wien; F. Quensel, Leipzig; M. Rothmann, Berlin; H. Schlesinger, Wien; S. Schönborn, Heidelberg; H. Starck, Karlsruhe; H. Steinert, Leipzig. Herausgegeben von Dr. Hans Curschmann, Dirigierendem Arzt der Innern A teilung des St. Rochus Hospitals in Mainz. Mit 283 in den Text gedruckten Abbildungen. Berlin: Verlag von Julius Springer, 1909.

The names associated with the production of this manual of nervous diseases are sufficiently well known, for the most part, not to require an introduction to American readers of German text. The idea of having the various parts of the book prepared by writers who had made special studies and investigations along the special lines of subjects assigned to them was the conception of Dr. Curschmann. The resulting volume is valuable and authoritative, though perhaps a little too conservative respecting the very latest suggestions in diagnosis and treatment. There is no bibliography and comparatively few references appear in the text. The book is intended for the student and general practitioner rather than for the specialist. The intimate relation of neurology with the other branches of medicine seems to be kept in mind by most of the collaborators, and this is important. The book really comprises a series of twelve concise monographs, which have been carefully edited, so as to comprise a harmonious whole. Curschmann has written especially on the myopathies and the vasomotor and trophic disorders; Schoenborn, on general diagnosis; Steinert, on diseases of peripheral nerves; Rothmann, on the physiology and pathology of the cord; Liepmann, on the physiology and pathology of the brain, etc. The organic nervous diseases of childhood form a separate division; also psychasthenic states (by Aschaffenburg) and toxic conditions (by Quensel). One of the best chapters is the last, by F. Krause, on operative treatment in nervous diseases. In this are described craniocerebral topography and various operations on the brain for decompression, or for the removal of tumors, cysts, abscesses, etc. Then follows a brief consideration of operable conditions of the cord and of the peripheral nerves. This chapter might be further elaborated. The book is well illustrated, and reflects credit on the publishers in its handsome appearance.

Atlas zur Mikroskopischen Diagnostik der Gynäkologie; nebst einer Anleitung und erläuterndem Text. By Priv. Doz. Dr. Rudolf Jolly, Oberartz der königl.-Universitäts-Frauenklinik zu Berlin. Containing 52 colored lithographic plates. Berlin: Urban & Schwarzenberg. 1910.

One of the most marked advances in modern gynecology is the recognition accorded to the value and necessity of microscopical diagnosis. Although the problems connected with this subject have by no means all been solved, a satisfactory basis for interpreting this class of microscopical findings has been devised and is now in fairly general use. To Olshausen must be given the credit for first calling the attention of the profession to the value of examining uterine scrapings in the differential diagnosis of certain conditions, from which these methods have since developed. The latest and most complete contribution to the science of microscopical diagnosis has just been brought out in the form of an illustrated manual by Jolly, who has had an extended experience with the subject as an assistant in the pathological department of the "Frauenklinik." His book consists of a series of over fifty lithographed plates in which are represented the dominant microscopical features of the leading gynecological lesions. This is preceded by a brief chapter on the technique of the examinations. The plates themselves are carefully executed, and portray the findings in endometritis, ulcerations, and erosions of the cervix, carcinoma, sarcoma, and polypus. The histological conditions associated with menstruation and pregnancy are likewise pictured. Each plate is accompanied by a brief description of its principal features. Jolly's book is a most valuable contribution to gynecological literature.

The International Medical Annual: A Year-book of Treatment and Practitioner's Index. 1910. Twenty-eighth year. New York: E. B. Treat & Company.

This year-book, which now appears for the twenty-eighth time, is devoted chiefly to treatment. Among the most striking of the articles is that on "injections of sea water," the illustrations "before" and "after" showing most gratifying results following this mode of treatment. Other important articles are those on appendicitis, brain surgery, cancer, cataract, diseases of the ear, eye injuries and affections, heart diseases, surgery of the intestines, mental diseases, peritonitis, diseases of the rectum, diseases and surgery of the stomach, syphilis, tuberculosis, typhoid fever, urinary deposits, and diseases of the uterus. It is difficult to imagine a practising physician to whom this volume would not be of real service. A large amount of medical literature has been sifted, and only the valuable has been retained; this has been condensed and put in a form suitable for ready use, and the work has been done by experts on their special subjects.

La Toxémie Neurasthénique. Les Neurasthénies sont des Intoxications. Par le Dr. Maurice Page, Médecin Directeur de l'Institut Médical de Bellevue. Preface du Dr. F. Helme. Paris: Vigot Frères, Éditeurs, 1910.

Some writers would have us believe that in neurasthenia the mental symptoms so predominate that it may be considered an affection of the mind, and that it can be successfully treated by psychological methods. Others state that it is always a physical disease, due to physical causes, the relief of which brings about a cure. Savil was among the first to point out the role which autointoxication plays in the causation of neurasthenia. The present writer, in a study of 200 cases, concludes that all true cases of neurasthenia are toxic in origin, and treatable on that basis. His book is worth reading.

Epidemic Poliomyelitis. Report of the New York Epidemic of 1907. By the Collective Investigation Committee. Dr. B. Sachs, Chairman. Dr. E. T. Zabriskie, Secretary. New York: The Journal of Nervous and Mental Diseases Publishing Company, 1910.

This pamphlet, which is No. 6 of the Nervous and Mental Disease Monograph Series, is a report of the work done by the commission during and following the epidemic of 1907 in New York City. The volume consists of five papers: I. Epidemiology of Poliomyelitis. II. On the Conditions Preceding Onset and the Early Symptoms of the Disease. III. The Symptomatology of Epidemic Poliomyelitis. IV. The Pathology and Pathological Anatomy of Epidemic Poliomyelitis, and V. Treatment of Poliomyelitis. The book is probably the most comprehensive work upon the clinical and pathological aspects of this disease of childhood. It is, however, of especial interest as the basis of the later work upon the subject from the experimental side which has made such tremendous strides during the past two years.

The Essentials of Chemical Physiology. For the Use of Students. By W. D. Halliburton, M.D., LL.D., F.R.S., Fellow of the Royal College of Physicians, Professor of Physiology in King's College, London; Author of "Text-Book of Chemical Physiology and Pathology." Seventh Edition. London, New York, Bombay, and Calcuttta: Longmans, Green & Co., 1909.

This well-known book has been revised and brought up to date, so that it still remains a practically indispensable volume for the medical student. The practitioner will also find in it an authoritative *résumé* of all that is important in this progressive subject. Besides numerous additions and alterations, this revision contains a new chapter on some typical organic compounds. By judicious elimination of antiquated matter this edition is little, if any, larger than its predecessors; this is an important matter, but one generally overlooked by authors and editors.

Pocket Therapeutics and Dose-Book. With Classification and Explanation of the Actions of Medicines, Doses in Troy Weight with Metric Equivalents, Genitive Endings of All Medicines and Preparations Given in Italics, Index of Common and Pharmaceutic Names, Index of Diseases with Remedies, Tables of Solubilities, Illustrations and Examples in Prescription Writing; Poisons, Their Symptoms, Antidotes, and Treatment; Incompatibles and Antagonists, Useful Hints to the Prescriber. By Morse Stewart, Jr., B.A., M.D. Fourth Edition, Rewritten. Philadelphia and London: W. B. Saunders Company, 1910.

The contents of this tiny volume are indicated on the title page, as printed above. Its chief use will probably be as a dose-book, and the space devoted to this part of the book is about two-thirds of the entire volume. It is a pity that the book has to be turned round before the doses can be ascertained. With the exception of the Therapeutics we have nothing but praise for this work, but the Therapeutical sections are too sketchy to be of any service to any reader.

Society Reports.

MEDICAL SOCIETY OF NEW JERSEY.

One Hundred and Forty-fourth Annual Meeting, Held at Atlantic City, June 28, 29 and 30, 1910.

The President, Dr. Benjamin Waddington of Salem, in the Chair.

Report of Committee on Prize Essay.—Dr. Charles J. Kipp, chairman, reported that the prize of $100 had been awarded to Dr. Elbert S. Sherman of Newark for a paper on ophthalmia neonatorum. This committee offered many recommendations for the dissemination of knowledge for the purpose of prevention of blindness caused by ophthalmia neonatorum.

Address of Welcome.—Mayor F. P. Stoy welcomed the members of the association and said that the doctors did more for Atlantic City than any body of men. He gave them a hearty welcome and offered them the freedom of the city.

Address of Welcome.—Dr. E. H. Harvey, President Atlantic County Medical Society, welcomed the members of the Medical Society of New Jersey.

When and by Whom Should Surgery Be Advised.—Dr. John B. Deaver of Philadelphia delivered the oration on surgery. He discussed the relations of specialist and practitioner which were best calculated to secure the greatest efficiency of the profession against disease. He pointed out by a brief historical sketch that specialism was an unfailing accompaniment of advancing society, but admitted that it was not an unmixed blessing. The paper dealt chiefly with the relation of the surgeon and practitioner. The latter was in the strategic position as regards the patient, therefore his attitude toward surgery and toward the individual surgeon was most important. The occasional surgeon was condemned and Billing's remark was quoted with approval that "he would not have anyone operate upon one of his patients whom he would not have operate upon himself." The requirements of both medicine and surgery in respect to both time and knowledge were so exacting as to make necessary a severance of treatment. The crux of the matter was in the question "at what point of time should physician and surgeon meet to secure the best result." The old plan of the physician reserving judgment for himself and using the surgeon merely as a pair of skilled hands has signally failed. It was, however, an idea which was dying hard. It was forcibly pointed out to what extent surgery was rewriting chapters of medicine which were written by internists. Osler's new "Practice" contained many instances and in his remarks on peptic ulcer he was quoted as saying that "what the modern 'gastroenterologist' needs is a prolonged course of study at such clinics as Rochester or Leeds." The rôle of ulcer as the exciting cause of gastric cancer was one of the most valuable aids to preventive treatment of this disease and had been entirely determined by the surgeon. The surgeon was defined as a specialist in surgical diseases and not as an operator. When the practitioner rid himself of the idea that the surgeon was going to say operate in every case he saw there will be fewer falities from unwarrantable delays. The constantly diminishing mortality of surgical interference was adduced as an argument for more frequent consultation. For how could the advisability of an operation be affirmed or denied without light upon the important point, for after all our advice to patients was based upon no absolute assurance but only upon relative degrees of safety. No man who was not in constant touch with the subject could keep pace with changing surgical risks. It was not at all infrequent to find older men in practice who were appalled by their idea of the risks of an operation that nowadays had almost no mortality. A plea was made for more careful consideration of diseases of the stomach, gallbladder, pancreas, and appendix, the disturbances due to which were so often classed as simple indigestion. The surgeon's experience in intraabdominal pathology made him to-day a safer doctor for a patient who had abdominal diseases than was the internist since it was the unrecognized surgical diseases that killed. Preventive surgery should be more often invoked, meaning not the surgery on normal organs, but upon those in which a disease process was in motion which experience told them was likely to have disastrous consequences. A difficult operation should not be regarded as a sign that it was necessary, but as a reproach that the optimum moment had been allowed to pass by. An easy operation meant an easy and safe convalescence. The solution to the question propounded was to be found in the indidvual case by cooperation of physician and surgeon. The knowledge of the former as to the pecularities of the case was indispensable and when joined to the special knowledge accumulated by the surgeon an answer would emerge easily and naturally as a result of mutual understanding and agreement. For every operation there should be several consultations instead of many operations to every consultation as at present. By this union of council it was thought that the best interests of the patient would be conserved, precipitate surgery would be checked, and likewise eleventh-hour operations be relegated to the past.

Empyema.—Dr. Irwin H. Hance of Lakewood reported his personal experience with two cases of emypema. The operation in acute cases should be immediate resection of one or more ribs. One or two aspirations without great delay before resection of the ribs might be worthy of consideration, but was generally bad surgery.

Dr. Frank D. Gray of Jersey City said that the frequent results of the routine treatment of emypema amounted probably to what might be called an opprobrium of surgery. Many cases go on to the formation of old sinuses, persistent suppuration, sepsis, amyloid degeneration of the kidney, and many of them to death. Among the reasons for such results he mentioned an imperfect diagnosis, and an imperfect treatment. Beck's bismuth paste would often help. He advocated what Murphy of Chicago recommended, the aspiration of the fluid and the injection of a 2 per cent. formalin solution in glycerin.

Dr. Henry L. Coit of Newark believed that when pus was found in the pleural cavity it should be at once removed. He reported two cases, both sequelæ of influenza.

Dr. McCoy of Paterson believed that the bad results in these cases were due to inefficient treatment, especially the surgical when the openings were not free enough. He had treated eight or nine cases with Beck's bismuth paste, but he had not found it efficient in the old chronic cases. He thought lung gymnastics of great value.

The Early Recognition and Diagnosis of Organic Disease of the Nervous System.—Dr. William M. Leszynsky of New York read this paper. He said that the primary cause of many avoidable errors in diagnosis was the neglect of the general practitioner to avail himself of the advantages of acquiring a knowledge of the fundamental principles of neurology. Hence, the unfortunate and prevailing tendency to carelessly ascribe many obscure symptoms to hysteria and neurasthenia, while evidence of organic disease was unmistakable. A classical case of tabes dorsalis, paralysis agitans, spastic spinal paralysis, myelitis, or general paresis was quickly identified. What they were all striving for, however, was to make the diagnosis at the earliest possible moment before the disease was fully established. The recognition of organic disease of the nervous system in its incipiency was an opportunity and privilege that the general practitioner had failed to cultivate. Tabes dorsalis and intracranial tumor had

proved a perpetual source of more serious errors than all of the other organic diseases combined. The non-recognition of tabes was more frequent than its diagnosis. Many years of observation and association with physicians had impressed him with the fact that the testing for the knee-jerk and reaction of the pupils was either inaccurately or carelessly performed. Dr. Leszynsky also spoke of the importance f making an early diagnosis of general paresis. In his opinion, delay was dangerous, for many of these patients could be practically cured by suitable treatment if the disease was recognized in time. He also dwelt upon the value of the Wassermann reaction, and believed that they should be cautious in depending upon it exclusively. In the diagnosis of brain tumor ophthalmoscopic examination was often neglected on the ground that there was no impairment of vision, which was a very serious mistake In all suspected cases of intracranial disease, the eyegrounds should be examined frequently Several instances were cited in which optic neuritis developed within a few days after the nerves had been found normal The importance of other symptoms including the Babinski plantar reflex was also dwelt upon, as well as the danger of mistaking the cerebral symptoms in chronic nephritis for those of brain tumor

Acute Pyelitis in Children.—Dr. George B. Philhower of Nutley reported the histories of six cases of acute pyelitis, all females, and five of these six cases had influenza. The diagnosis of these cases rested on the microscopical examination of centrifuged urine.

Dr. Henry L. Coit of Newark believed it was very important to recognize the fact that the innocent character of the colon bacillus might be changed into a type which was not only vicious but virulent. A consideration of the portal of entry was of importance. In the treatment of these cases he emphasized the three "Ws," water, wait, and watch, with the administration of urotropn, if you wanted to use it.

Dr. J. Finley Bell of Englewood discussed the bacterial cause of pyelitis. The color bacilli would be found in the urine of all babies, if the urine be cultured. If the doctor waited for a chill in these young children before making a positive diagnosis he would be disappointed.

Report of the Delegates to the International Medical Congress at Budapest; also of the Delegates to the Convention on the Ninth Decennial Revision of the United States Pharmacopea.—Dr. Henry L. Coit of Newark made this report:

A Plea for a Higher Standard of Medical Education.—Dr. Benjamin A. Waddington of Salem delivered this, the president's annual address. He said that it must be recognized that the spirit of the age was one of progression ruthlessly stimulated in all the walks of life by the keener competition, individually and collectively, and this meant that he who would be measured successful in the struggle for existence or in gaining or regaining of even a modicum of the favors and smiles of Dame Fortune must be armed cap-à-pie with all the possible advantages in entering the list for preferment in his chosen vocation. At this period of the world's revolution all the various walks of life demanded more and more of the man; and further this demand would go forward with herculean bounds; the wisdom of to-day would be the foolishness of to-morrow, the high standard of the now would be the minor height of the then. In asking of those who would be of the priesthood in the temple of Hygiea certain advanced preliminary educational requirements before admitting them to the study and practice of the rites of the Goddess, they were but following in the footsteps of what past ages in all guilds had required and imposed upon the neophytes who would partake of the knowledge of the inner mysteries of the shrine. It was to be regretted that the profession *en masse* did not set a standard for the admission to its body at the very highest possible notch and then see that those who would be of us measured rightly in the gauge. Medical men in the language of the day seemed to lack the grit to enforce these views and seemed afraid in this as in many other abuses of their profession to speak out manfully and to strike from the shoulder at what did or would detract from their high calling. The reason why the physician did not occupy the elevated place in the esteem of the community he wanted to was that he did not compel a higher respect for his profession from the laity by the prevention of its attaining by incompetents and thus showing a respect for it and for himself. The time would never come in this country, probably, when all doctors of medicine must be graduated from the same college; but the equivalent of it might be required, however acquired. Nevertheless, he who could acquire the necessary funds to take him through college, and was not too old when he began to develop his faculties and gain a standing in the intelligent world, should in every instance take a college course.

Oration in Medicine.—Dr. W. Gilman Thompson of New York City delivered this oration. He said that during the past two or three years notable advance had been made in many of the broader aspects of medical science, and achievements had been accomplished which were of world-wide importance. Among these might be reckoned the discovery of the widespread distribution of hookworm disease; the recognition of pellagra as a menace to our national health; work of Colonel Gorgas in the abolition of yellow fever and of the gravest forms of malaria from the Canal Zone; the ability of the Quarantine and Marine Hospital services to deal effectively with bubonic plague and other serious affections, etc. Moreover, the net was drawn closer around cancer. Never before had our National and State organizations been so efficiently organized and productive of the highest scientific results. Although the measure had been temporarily defeated, the President and at least one of the great political parties stood definitely committed in favor of establishing a National Health Department. A medical society like that of the State of New Jersey should occupy the position in the community of a clearing house or court of appeal in all the broader aspects of medical science in so far as they concerned the general public interests and the public should become accustomed to seek its advice and trust its decisions. There were many urgent problems waiting to be assailed systematically, such as the extermination of typhoid fever and malaria, the disposal of town sewage, the control of the milk supply, the limitation by education of the social evil, the questions of school hygiene, modern hospital construction, and the limitation of the great and increasing variety of occupational diseases. The speaker referred to the way that some of these problems were being worked out in New York State. He mentioned the work being done in hospital erection. The idea was new that the hospital should be adapted structurally for the treatment of disease, and not as a mere dormitory where the sick were all placed under precisely the same conditions of environment. This structural adaptation consisted in having almost as much of the building outside of its walls as inside. As much space was required for administrative, therapeutic, and laboratory purposes as for the mere housing of the sick. He strongly urged administrative cooperation between hospitals, both in regard to proper distribution of patients and economy in purchasing of supplies. A State society might accomplish a great deal of good by maintaining a permanent hospital committee of experts, charged with collecting data and furnishing information and advice to those contemplating the erection of hospitals.

The Significance of the Agglutinating Power of the Blood Serum During and After Typhoid Fever.—Dr.

Geo. T. Welch of Passaic said that there was an impression abroad among the laity that, so long as the Widal test gives the typhoid reaction, there were typhoid bacilli remaining in the system of the individual from whom the cuture was taken, and that he was a menace to the health of the community, and that some measure should be taken to isolate him from his fellows. Sensational reports in the daily newspapers of typhoid carriers had disordered and made apprehensive the public mind on this subject. It was true that bacteriologists had occasionally reported the presence of typhoid bacilli in the contents of the gallbladder and in the urine of persons some time after they had recovered from all the usual clinical manifestations of typhoid fever, but this was most unusual. On the other hand, it was the usual matter of observation that, while the Widal test was found inoperative for the first five to eight days in a case of genuine typhoid fever, it might be found to produce agglutination from that time on for months, or even for two years or more afterward. The reason of this was that the blood serum of a case of typhoid fever could not produce agglutination of the typhoid bacilli until nature had sufficiently propagated the antagonistic bodies that neutralized the disease germs in the system of the patient, which occur about the end of the first week; but, having reached this point, overproduction of these antagonistic bodies continued for an indefinite time, and rendered the blood serum capable of agglutinating long after the disease had subsided. And, while these antagonistic bodies remained, the individual that harbors them was immune from typhoid fever. He might carry colonies of typhoid bacilli in his gallbladder for a varying length of time without any toxic effect upon himself, for the reasons given, and instead of there being a relapse in typhoid fever, except in some rare instance which one might admit, but not demonstrate, it was a recrudescence of fever of another kind, caused by autointoxication from injudicious feeding, and usually was a short course, with recovery as the rule. This immunity was associated with the acquisition by the body fluids of a specific germicidal power. Typhoid bacilli introduced into the peritoneum of an immunized animal were speedily disintegrated and dissolved. And this was a strong argument for the use of immunized serum by injection into the typhoid patient early in the disease. By this means they should be able to neutralize the toxins of the diseases, and abort the fever. The slow-developing antagonistic bodies might be fortified and stimulated, and made to speedily overwhelm the typhoid bacilli, and thus rescue the patient much earlier from his dangerous position.

Personal Experience in Renal and Urteral Surgery.—Dr. George N. J. Sommer of Trenton made a report of test cases, comprising renal calculus, with and without pyonephrosis, renal tumors, septic infarction and ureteral calculus.

Surgical Mishaps.—Dr. Frank D. Gray of Jersey City read this paper. Mishaps in surgery, he said, were of two general classes, one of diagnosis and the other of technique. Each again might be subdivided into the excusable and the inexcusable, the latter, strictly speaking, *blunders*. To pronounce a stomach lesion cancer, after a careful consideration of the history, symptoms, physical signs, blood analysis, and chemical tests, coupled with deliberated valuation of all the evidence and logical exclusion of improbabilities, and then on operating to discover a chronic ulcer was a diagnostic mishap which might befall the best. To do a nephrectomy and find at autopsy that one had removed the patient's only kidney, when cystoscopy and ureteral catheterization would have revealed this fact showed a diagnostic weakness amounting to a blunder. To divide a ureter while extirpating a laterally misplaced uterus was a technical mishap which none might always escape. To leave a sponge or artery forceps in the peritoneal cavity for lack of a final count or a ligature of a septic appendix with nonalbsorable material was a technical blunder that should never have occurred. Consideration of this subject, perhaps, might be facilitated by reviewing it somewhat according to the regional anatomy. Dr. Gray said that his surprise was great, on one occasion, when he expected to remove a chronically inflamed appendix that had apparently caused two distinct attacks and which could be felt as an induration under the examining finger, to find a normal appendix but an inflamed undescended ovary. This incident was not serious, for surgical intervention was indicated; it was, however, rather humiliating to his diagnostic pride and served to emphasize the fact that many other things aside from the appendix might cause pain in the southwest corner of the abdomen. As was understood, the thoracic organs, lungs, and pleura, through reflex influence, were occasionally responsible for surgical mishaps in the abdomen, as when a pneumonia or pleurisy led to operation on a supposed appendicitis. The reverse happening was not so common, but nevertheless occurred. A hospital patient was admitted with evident general peritonitis, apparently secondary to appendicitis. The history was of a two days' illness and he had walked to the hospital from some distance. Dr. Gray noticed that the respirations were fifty to the minute. This suggested a pulmonary complication and he found a higher line of dullness over the lower chest than the liver would account for. Naturally suspecting a secondary empyema he introduced a needle and withdrew a syringe full of pus. Having settled the diagnosis positively, as he supposed, he began the operative procedure by doing a thoractotomy. The pleura was absolutely normal. The elevated line of dullness was the liver, pushed up by abdominal distention. The needle, introduced rather low down, had gone through the diaphragm and drawn pus from the peritoneal cavity, which was swimming with it. Thus, apparently, positive findings would trip them through unwarranted interpretation. Another point of interest in this case was that no appendicitis existed, but a perforated typhoid ulcer. More care in taking the history would have shown, as was afterward learned, that the patient was really ill for two weeks before admission to the hospital, but actually ill only for two days. In other words, walking typhoid for two weeks, perforation and acute general peritonitis for two days. Perhaps no abdominal or pelvic organ had been responsible for more inexcusable diagnostic and technical mishaps than the bladder. "Never forget the bladder" was advice frequently neglected. A humiliating incident in his own experience was along this line. A woman of the unfortunate class was brought to the hospital from an industrial home. She had been on a prolonged debauch and was suffering severe, intermittent abdominal pains. An enlarged abdomen comported with a seven months' pregnancy and was flat to the umbilicus but fluctuating. The vagina was almost obliterated by a bulging of the posterior wall which also fluctuated. The cervix was high up anteriorly and the body of the uterus was not palpable. The intermittent, bearing down pains suggested a pregnancy with impending miscarriage, but from the physical signs he thought there was a complicating large ovarian cyst and he ordered preparation for laparotomy. When about to begin the operation he was asked by a spectator if a catheter had been used. It had not. He had ignored the bladder, being told by the nurse that the patient voided. The catheter was introduced and *two gallons* of urine were withdrawn. The tumor disappeared, the pains ceased and he said he was saved more than a humiliation. During her intoxication the woman's bladder had become overdistended and paralyzed, with consequent overflow that had been interpreted as a normal urination. Dr. Gray said he had since seen two other cases in which the female bladder held, without rupture, respectively six quarts and a washbowlful of urine. Any physician who

had had one experience of this sort would always beware of the bladder. The female viscus would hold almost any quantity short of a buckful; not so the male, as was proven on one occasion when he attended a man who also had been intoxicated for days and whose bladder had ruptured with severe extravasation of urine from a phimosis-stricture of the foreskin, if they pleased. A mishap of transfusion was worth mentioning in passing. A coagulum might form in a Brewer tube if the lumen be not thoroughly paraffin coated. The accident happened in the first of his case and the transfusion ceased after seven minutes' donation of blood. To avoid coagulum the tube should be prepared by not merely dipping it in melted streilized paraffin, but should be allowed to remain submerged until all tiny air bubbles cease to rise. In this way the lumen was completely filled. When a quick, sharp shake of the tube would divest it of surplus paraffin was then ready for use and would disappoint. Surgical mishaps in the region of the head and neck were perhaps only second to those of abdominal surgery on account of the possibilities afforded by traumatiisms and pathological conditions of the brain, organs of special sense, accessory sinuses, vessels, and glands. A diagnosis of brain lesions depended so largely upon accurate and perfect knowledge of complicated focal symptoms that the general surgeon would avoid many mishaps were he to secure the help of the neurologist in such cases. In traumatic cases, however, the surgeon had at least one superior resource, the exploratory incision. The following case illustrated the importance of immediate explorative operation. A man was struck over the head with a hammer on the upper forehead and over the right parietal region. A probe struck denuded bone in each place, but he could not demonstrate a depression in either location. A free enlargement of both scalp wounds showed no fracture in the forehead, but on the top of the head was a comminuted fracture the size of a coat button, both tables being depressed a quarter of an inch. No pressure symptoms indicated this and there probably would have been none. Yet here was a traumatism that offered a fine prospect of later epilepsy. To-day the man was none the worse except for two good-sized scars on his scalp. Concerning surgical errors in the extremities, fractures perhaps were usually not buried but survived to confront and dismay the surgeon. At the same time the recognized value of the *x*-ray in the diagnosis and of modern operative treatment left the surgeon little excuse. A badly functionating leg from fracture of the patella without operation was near malpractice, but a stiff knee, on the other hand, as a result of operative procedure was in the same category. "Silver fork" deformity from Colles' fracture was practically inexcusable since reduction was the crucial matter, and reduction could be accomplished under anesthesia. The supreme importance of anesthesia in the reduction of fractures and dislocations, and the proof by radiograph, must ever be borne in mind. It would pay not only in ease of mind but in dollars and cents. That fracture of the upper or lower third of the femur must be treated on a double inclined splint with Buck's extension was recently brought forcibly home to him. He made the not rare, but inexcusable, mistake of accepting a previous diagnosis, the cause of many mishaps, and left such a fracture in a man seventy-five years old as he found it, in straight Buck's extension, with the result that his successor discovered a bad deformity and non-union. His chagrin was only mitigated by securing the privilege of resecting and wiring the ends of the bones with excellent result despite the patient's advanced age. Allusion to his confidence in surgery of the knee joint made him say that while he believed in it he also feared it almost more than anything else; fear did not prevent his doing it, but made him enforce all the details of the most rigid asepsis. His nearest approach to a mal-practice suit was on account of an ankylosed knee after an operation on a clean case. He said he was saved by the ethical conduct of a fellow member of the Medical Society of the State of New Jersey who told the patient, when approached for an opinion, that it might have happened in his own practice, or that of any other surgeon, a spirit to be commended to all in the presence of other mishaps.

The Spontaneous Cure of Malignant Disease with History of a Very Unusual Case.—Dr. Alexander Marcy, Jr., of Riverton read this paper. The term "malignant" applied particularly to carcinoma. Was carcinoma ever spontaneously cured? He believed it was, because there was a sufficient number of cases reported to substantiate such a statement. How such cures were accomplished he could not say with any certainty. Dr. Marcy also reported a case that was symptomatically cured. He referred to other cases that had been reported in the literature from time to time. It seemed that from such reports it had been proved that cancer had been cured spontaneously.

Dr. Edward J. Ill of Newark reported a case of cancer of the liver of undoubted authenticity in which there was a spontaneous cure.

The Ophthalmia of the Newborn, Its Causation, Prevention, and Treatment.—Dr. Elbert S. Sherman of Newark read this, the prize essay. He said that notwithstanding the fact that ophthalmia neonatorum was a preventable disease, over 25 per cent. of the pupils admitted to the schools for the blind were there from this cause. About 65 per cent. of the cases were caused by the gonococcus, 10 per cent. by the pneumococcus, 10 per cent. by other pathogenic organisms, and 15 per cent. were negative bacteriologically. The eyelids became contaminated during the passage of the child through the vagina and the actual infection of the eyes usually occurred after birth for, in the majority of the cases, the lids at birth were closed and sealed. That the Credé method was effective when properly carried out there could be no doubt. That is was not employed by many physicians in private practice was well known. Midwives were not to blame for all the cases. Many occurred in the practice of physicians. Statistics on this subject were practically all based on hospital work. To ascertain the true conditions in private practice the writer of the paper said he interviewed fifty acquaintances in active general practice. As to their methods of prophylaxis, these physicians might be divided into three classes: (1) Those who either gave the eyes little or no attention, or who relied upon simple cleansing and seldom or never used prophylactic drops. (2) Those who used the drops in suspicious cases. (3) Those who usually or always used the Credé or modified Credé method. Their combined experience was tabulated. There was a total of over 45,000 births. Thirty-three physicians were in the first class, and only eleven in the third class. The results in class three were better than the results in class one. It had been demonstrated that simple, careful methods of prophylaxis gave results almost as good as the best results of the Credé method. But in the large majority of the cases in private practice, and always in hospitals, drops should be used in the eyes soon after birth. The consensus of opinion was now in favor of a 1 per cent. solution of silver nitrate as the proper prophylactic agent. Prophylactic measures were often ineffectual or carelessly carried out. Secondary infections by means of contaminated towels, ben linen, dirty fingers, etc., must be guarded against. At the first bath separate water should be used for the face and care taken to prevent any bath water entering the eyes. Infections frequently occurred during the first bath. If the treatment was begun early the prognosis was good. It required much faithfulness on the

part of the attendants and should be supervised by one skilled in the treatment of diseases of the eye.

Election of Officers.—*President,* Dr. Thomas H. Mackenzie of Salem; *First Vice-President,* Dr. Daniel Strovk of Camden; *Second Vice-President,* Dr. Hollingshead of Pemberton; *Corresponding Secretary,* Dr. Harry A. Stout of Wenonah; *Recording Secretary,* Dr. William J. Chandler of South Orange; *Treasurer,* Dr. Archibald Mercer of Newark. Meeting in 1911, Asbury Park, June 27, 28 and 29.

Report of the Committee on Legislation.—Dr. Luther M. Halsey of Williamstown said that at the last session of the Medical Society of the State of New Jersey a committee was named to act in conjunction with the committee on legislation to frame a Medical Practice Act. After several conferences they decided that they had a bill ready to be presented and which was in good shape. The Governor said that if the educational requirements were made too high the bill would be vetoed on the ground that it would be impossible for any person to receive a medical license in this State unless he had unlimited finances at his control. After the bill had been placed in the Governor's hands those who waited upon him were curtly informed that he proposed to have a hearing on this bill. The history of this hearing was probably very well known. There was no question in their minds that the Governor had been antagonistic in every way to the medical profession during his term of office. They were quite sure that affairs were in such a condition in New Jersey that a good medical bill would pass at the next session of the Legislature beyond a question, and if the proper man occupied the office of Governor they would see placed upon their statute books a law which all would be proud of. The committee had always taken the stand that osteopathy was a fake; that their schools were far below the standard. They should insist that all practitioners of the healing art should comply with the rigidly enforced preliminary standard; that every school should possess the requisite facilities; that every licensed physician should possess a broad knowledge of the body and its affiliations. The midwifery bill which was vetoed by the Governor during the session of 1909 was passed this year. The ophthalmis neonatorum bill was successfully passed. The Optometry bill was defeated. During the legislative conference in Chicago, the unanimous opinion of the delegates was that, by the enacting of a Medical Practice Act, it would be necessary to bring about reciprocity between all States. They should bring about a plan of education and publicity; they should take the people into their confidence; they should show them what they desired to accomplish; they should be educated along the lines of sanitation and in the causes of this warfare upon the great white plague. The medical men were in a position to teach, and it was their duty to be the educators of the people in these vital questions.

Dr. David C. English of New Brunswick offered a resolution, which was seconded and unanimously carried, condemning Governor Fort for his public insult to Dr. L. M. Halsey, chairman of the Committee on Legislation of the State Medical Society, and for his actions resulting in a lowering of the preliminary educational requirement for the license examination, as a consequence of which New York had refused further reciprocity in medical licensure.

Presentation of a Loving Cup.—Dr. L. M. Halsey presented to Dr. William E. Ramsey of Perth Amboy in behalf of the Medical Society of the State of New Jersey a loving cup on which was engraved the following: "To Dr. William E. Ramsay, from his medical friends as a token of appreciation for his devotion to the profession and the safeguarding of the lives of the people of the State."

Address by the Third Vice-President.—Dr. Norton L. Wilson of Elizabeth said that the Medical Society of the State of New Jersey had withstood the varying vicissitudes of one hundred and forty-four years, and to-day they were stronger in influence and numbers than ever before. It was important that all should familiarize themselves with legislation, in which they should have a deep interest. They should be more united. They came nearer being a unit in thought and in purpose when an outrageous and gratuitous insult was offered to the chairman of the Legislative Committee by the Chief Executive of the State. They resented his being called a liar even by one so high in authority, and felt that not only they as physicians had been insulted, but the welfare of the people, whose cause they championed, had been utterly disregarded. The occurrence referred to united them in feelings of resentment and bound them together as a profession more strongly than before. He firmly believed they could accomplish much if they took the cause of the people to the ballot box. Dr. Wilson said that he had repeatedly asked his confrères if they believed in the theory of osteopathy, and almost invariably they would say they believed those who practised in accordance with that theory did some good. There was reason to expect such an answer from the laity, but not from scientific men who should know the theories of osteopathy. Medicine had attained the dignity of a science, and was no longer an art. Dr. Wilson made some remarks on the theory of osteopathy. The osteopath of to-day was not satisfied with simple manipulation; he wanted to do surgery and use means other than his natural faculties.

The Relation of the Public to and the Obligation of the Physician in the Development and Spread of Bacterial and Epidemic Disease.—Dr. Philip Marvel of Atlantic City read this paper. He dwelt more particularly upon the attitude toward the cause and development of certain diseases, which attitude was only of late generally known to be strongly antagonistic to the establishment of prohibitory restrictions which insured protection against these diseases. He said that if he were asked to name the most important factors involved in promoting the influences which were responsible for the present situation he unhesitatingly would say that they were particularly three in number: (1) The commercial interest, which too often disregarded all the rights and privileges of others, and which contributed most support to the object to be obtained. (2) The ignorance of the public as related to the cause and development of disease and the laws of hygiene and sanitary science. (3) The indifference and jealousies of most of the profession, whose lack of proper appreciation of the scope of the work comprehended or whose personal indifference to its source prevented them from a hearty cooperation with the prosecution of the great propaganda. Once the public was sufficiently aroused to comprehend and appreciate its own interests in this great question, little assistance would be required in gaining possession of those rights. At no time in the history of civilization had there been so many proper and well directed educational measures for the uplifting of the people as existed to-day. After having introduced some of the immediate claims on the obligations with which the physician was charged, Dr. Marvel devoted the remainder of his time to the practical considerations of means for the removal of the common nuisances and active causes in the development and the spread of some of the more common and well known communicable diseases. He confined himself particularly to typhoid fever, tuberculosis, dysentery, and malaria. Epidemiological studies of the various communicable diseases had added to their knowledge of the spread of disease by both animate and inanimate carriers. Many crawling, creeping, and flying insects were extremely active in the spread and the development of typhoid fever, tuberculosis, and

other types of disease. Other carriers, as the rat and flea, were agents in the dissemination of plague; the cow and other animals in the spread of tuberculosis; the cat and dog in the transference of diphtheria and hydrophobia; fowl and pigs in the dissemination of the hookworm; the buzzard and other necrophaganous birds in conveying anthrax; man himself was not exempt from being a direct transfer agent of many infections. It was a disgrace that about 350,000 of the population were permitted to become afflicted with typhoid fever yearly, with a loss by death of about one-ninth, or 35,000; while more than 1,500,000 tuberculous cases were constantly seeking relief, and at least one-eighth as many contracted pneumonia. It was his firm belief that these infections would continue with little variation until the public was properly awakened and educated in reference to individual protection and duty.

Dr. Waddington announced that Dr. William H. Welch of Baltimore, president of the American Medical Association, was present and extended to Dr. Welch an invitation to make an address. Dr. Welch spoke chiefly on medical practice and license laws.

Milk.—Dr. Alexander McAlister of Camden said that milk was a medium for almost every form of germ life, and especially for the tuberculosis germ from infected cows. It has been asserted by Von Behring and others that many of the cases of pulmonary tuberculosis in adults were of tuberculous origin in infancy, the infection having occurred through the intestinal tract from drinking tuberculous milk. It was a known fact that fourteen out of every one hundred persons succumbed to tuberculosis, and that more than one-half of the remaining eighty-six show lesions of tuberculosis at post mortem. The dust and manure of the stables in which diseased cows were kept would contaminate the milk of healthy cows during the process of milking. Therefore, there was need of instruction, not only in regard to the milk but also in regard to the stable accommodations. The food products from milk should be inspected with equal vigilance. What should be done to purify the milk when it was produced under suspicious conditions? Pasteurization was the least expensive and most efficient available expedient. It destroyed certain bacteria and some of their toxic products. It also checked putrefaction. There was little doubt that the proper inspection of cows and cow sheds, regularly done, would do much toward the abolition of milk infection. Under any circumstances cow's milk should be pasteurized or boiled for children up to at least the age of five years. This was a wise precaution for any period of childhood. Raw milk was apt to be dangerous, and in pasteurization they had the only means of protection when they were in doubt about the raw product that was offered.

Adenoids; Their Influence Upon the Mental Condition of the Patient.—Dr. Joseph Koppel of Jersey City read this paper, the purpose of which was to impress the profession with the advisability of caring for cases of adenoids as early as possible. After giving a brief outline of the pathology of this condition he took into consideration the etiology which, in truth, was very vague and uncertain. Only lately medical inspection of schools had been established in Jersey City; they had tried to ascertain the mental condition of the children who had been excluded by the medical inspectors because they suffered from adenoids. Out of fifty (50) cases in one school all the teachers and principals agreed that all those excluded were below the mental average at their respective ages, twenty of them being backward in their work and the others far below the average. The following summary was offered: Aprosexia, or mental deficiency, was present in the children suffering from the effects of adenoids. Aprosexia was a natural consequence of the symptoms produced by adenoids, and only in the early diagnosis and the radical treatment of this condition could this enemy of the intellectual welfare of the children be eradicated.

Dr. Wells P. Eagleton of Newark said that during the last year there had appeared at the Eye and Ear Infirmary in Newark 461 cases of adenoids, all but 166 of which were associated with operations on the tonsils. He drew the following conclusions: (1) The condition of inattention and lack of power of concentration was infrequently seen in juvenile mouth breathers, and they were uniformly helped. The effect was immediate and striking. (2) In those young children, having the lymphatic tendency and bearing stigmata of degeneracy, the enucleation of the tonsils and the removal of adenoids was followed by most brilliant results. (3) The conditions called choreal, due as they frequently were to peripheral irritation, were not only greatly helped, but frequently permanently cured by the removal of the peripheral irritation. (4) In the congenital defects of mental development, the mental deficiency was bettered by the removal of the handicap to the general development. (5) He had seen a typical case of mental deficiency of the Mongolian type which showed a marked improvement following the operation for the removal of adenoids.

Dr. Norton L. Wilson of Elizabeth said that in 1887 Guye of Amsterdam first described the condition to which he gave the name aprosexia; he described a case in which the child of young age had learned the whole alphabet in one week following the operation for the removal of the adenoids. It was a noticeable fact that adenoids were found in a large proportion of idiots and backward children, but he was rather inclined to attribute these growths to the mental condition. In backward children he said that they had all seen marked improvement after the removal of the adenoids.

The Ethical Aspects of Expert Testimony in Relation to the Plea of Insanity as a Defense to an Indictment for Crime.—Dr. Carlos F. MacDonald of New York read this paper. (See page 133.)

The Nasal Accessory Sinuses and the Eye.—Dr. G. Harold Ward of New York read this paper. He reviewed the anatomy of the accessory sinuses and showed the intimate relations of the sinuses to the orbit, the eye, and the optic nerve, the symptoms of disease of the individual sinuses were given; this he followed by the known orbital complications from the different sinus diseases, collected from reported cases. From this data, supplemented by the report of a case of double optic atrophy in conjunction with obscure ethmoid disease, which might or might not have been the exciting cause, the following conclusions were reached: (1) In cases of visual disturbances, which had no apparent explanation, and in which sinus disease could be a possible factor, it should be proven conclusively that there was no latent sinus suppuration. (2) In cases of visual disturbance where sinus disease was present the possibility of accidental association must be remembered. (3) Sinus suppuration should be looked upon as a likely cause in cases (a) which reveal on opththalmoscopic examination neuritis, neuroretinitis, retinal phlebitis or hemorrhages, especially if monocular; (b) which, without opththalmoscopic signs, had visual disturbances, as central scotoma, limitations of visual fields, muscular paralysis, or functional disturbances of the fifth nerve; (c) in all inflammatory conditions of the orbit; (d) where the patient had a history, in any eye condition, of head trauma, or recurring colds following infectious diseases. In conclusion, Dr. Ward said that he had observed three cases of high myopia with fluid vitreous and opacities where ethmoidal and sphemoidal disease were present, but their pathological knowledge was still too incomplete to determine whether the sinus disease was the exciting cause or whether it was an accidental association.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Nevada State Board of Medical Examiners.

May 2, 1910.

ANATOMY.

1. Describe location and name the divisions of the osseous labyrinth.
2. What medictarsal joint is the weakest in the arch of the foot?
3-4. What bones enter into the formation of the ankle joint?
5. Give origin and insertion of the trapezius muscle.
6. What is the combined action of the gastrocnemius and soleus muscles?
7. At what point in the neck does the common carotid artery divide?
8. Give location and approximate length of the fissure of Rolando.
9-10. How many pairs of cerebrospinal nerves are there? Of those how many pairs are spinal?

PHYSIOLOGY.

1. Describe the process of osmosis and give examples in the human economy.
2. Describe urea, its occurrence, variations in quantity excreted, and recognition in the voided urine.
3. How can fresh blood stains be distinguished from older blood stains?
4. State where in the human economy the following substances are found: Fibrin, chondrin, leucin, hippuric acid.
5. In what manner is the heart beat influenced by the pneumogastric nerve? What is the average number of heart beats per minute in (*a*) a child one year old, (*b*) an adult seventy years old?
6. Describe the vermicular movement of the stomach and intestines. What purpose does this movement serve?
7. Describe the glands and villi of the intestines.
8. Locate in the brain the seat of the special sense of sight, hearing, and smell.
9. What would be the effect on digestion if the pancreatic duct were obstructed?
10. What is the office of the columnæ carneæ?

MATERIA MEDICA AND THERAPEUTICS.

1. What drug is antagonistic to pilocarpine?
2. State the source of ichthyol, and give its use in medicine.
3. Describe the therapeutic action of spigelia.
4. Describe the therapeutic uses and the dangers of chloral hydrate.
5. Give the chief source and the dose of gallic acid.
6. Describe the therapeutic uses of chromium sulphate.
7. Describe the treatment of cerebrospinal meningitis.
8. What are the therapeutic uses of strophanthus?
9. Correct the following prescription:

℞. Atropiæ sulphati .....grs. 1 ss.
Potas. iodidi .....½ oz.
Infusæ digitalis .....½ fl. oz.
Elix. simp. q.s. ad.....2 fl. oz.
M.
S.—Teaspoonful in water four times a day.

10. Give the theory of the alkaline treatment of rheumatism.

CHEMISTRY AND TOXICOLOGY.

1. Give chemical test for determining the presence of lactic acid in stomach contents.
2. Give tests in detail for indican in urine.
3. Give the chemical reason why diabetics should abstain from starchy foods.
4. Describe the test for detecting the presence of strychnine.
5. What is synthesis? Mention three coal-tar products extensively used in medicine that are prepared in the chemical laboratory by synthesis.
6. State the antidote to practically all alkaloids, explaining its action.
7. What is tyrotoxicon, and in what is it found?
8. What is the treatment for poisoning by wood alcohol?
9. What emergency treatment should be used for poisoning by laudanum?
10. Name a poison, in poisoning by which, fats and oils should not be administered. Explain.

PATHOLOGY.

1. Give the pathology of amyloid liver.
2. Differentiate between epithelioma and lupus.
3. Give the pathological changes occurring in a fracture of the skull at the base.
4. Give the pathology of the first and third stages of lobar pneumonia.
5. Give the pathology of erysipelas.
6. Give the pathology of pseudoleukæmia.
7. Give the pathology of tabes dorsalis.
8. Discuss the pathology of gallstone disease.
9. Give the pathology of acute gastritis.
10. Discuss the changes occurring in the spleen during an attack of typhoid fever.

BACTERIOLOGY.

1. How is yellow fever conveyed, and how would you prevent its spread?
2. How would you manage a case of typhoid fever in a country with very poor sanitary conditions to prevent its spread?
3. Describe and name the bacillus of diphtheria.
4. How would you detect the tubercle bacillus. Describe it.
5. Describe the *Streptococcus pyogenes* and *Staphylococcus aureus*, and where are they found?
6. What is meant by the terms antitoxin and immunization?
7. What do you know of the Noguchi method of the serum diagnosis of syphilis?
8. How is tetanus antitoxin prepared and how does it act?
9. Describe the *Streptothrix actinomyces*.
10. Describe the Gram method of staining for bacteria.

PRACTICE OF MEDICINE.

1. Discuss autointoxication.
2. Give etiology, symptoms, and treatment of dilatation of the heart.
3. Differentiate typhoid fever, malaria, and septicemia.
4. Describe the characteristic symptoms and course of morbilli.
5. What are the symptoms of abscess of the lung?
6. What is the etiology of progressive muscular atrophy?
7. Give the general symptoms of brain tumor.
8. Differentiate empyema from pulmonary abscess.
9. In what cases would the ophthalmoscope aid in diagnosis?
10. Describe a typical case of laryngismus stridulus.

OBSTETRCS.

1. Give the signs, approximate weight and length, and two principal diameters of the cranium of a fully developed fetus.
2. In what proportion to single fetuses do twins develop? Triples to single fetuses?
3-4. Give diagnosis of fetal syphilis. What particular sign is most suggestive and generally accepted?
5. Give treatment for inevitable abortion.
6-7. Give your technique in treatment of face presentation. What is the fetal mortality in such cases? What that of the maternal?
8. Give treatment of post-partum hemorrhage.
9-10. Give treatment for prolapsed cord. In whose position is it generally recommended that the patient be placed?

SURGERY.

1. Describe the anastomosis which takes place after ligation of the femoral artery at its middle third.
2. At what point is paracentesis thoracis preferably performed?
3. What is an adenoma? Give plan of treatment.
4. Through what channels is carcinoma disseminated?
5. Where is the swelling and fluctuation most prominent in synovitis of the ankle joint?
6. Give a classification, either original or from competent authority, of burns.
7. What are the conditions which render excision of the lower jaw advisable?
8. What are the complications of dislocation of the hip?
9. Name the varieties of shoulder joint dislocation.
10. What operations are performed for intractable neuralgia of the fifth nerve?

GENITOURINARY AND DERMATOLOGY.

1. Give the symptoms necessitating fixation of a floating kidney, and describe the operation.
2. Give the local treatment of venereal bubo.
3. What is hydrocele? Describe operations for its cure, and state your choice.
4. Describe syphilis in all its stages, and give treatment of each stage.
5. Give symptoms of stone in the bladder.

6. Mention the most common sites of epitheliomata.
7. What is xanthoma?
8. What are the causes and treatment of keloid?
9. What are the causes, symptoms, and treatment of bromidrosis?
10. What are the causes, symptoms, and treatment of pompholyx?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

Nevada State Board of Medical Examiners.

May 2, 1910.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), page 759; or Gray's "Anatomy" (1908), page 1174.
2. The astragaloscaphoid is the weakest mediotarsal joint in the arch of the foot.
3 and 4. The astragalus, internal malleolus (of tibia), and external malleolus (of fibula).
5. Trapezius. *Origin:* External occipital protuberance, and superior curved line of occipital bone, ligamentum nuchæ, spinous process of seventh cervical and twelfth dorsal vertebra. *Insertion:* Clavicle, acromion process, spine of scapula.
6. *Combined action of gastrocnemius and soleus:* To extend the foot; for use in standing, walking, dancing, and leaping; to raise heel and whole body.
7. The common carotid artery divides opposite the upper border of the thyroid cartilage.
8. Draw a straight line over the top of the scalp from the inion to the glabella; bisect this line, and half an inch posterior to the midpoint draw a line downward and forward at an angle of 67.5° for a distance of three and one-half inches. This line will represent the location of the *fissure of Rolando.*
9 and 10. There are thirty-one pairs of spinal nerves and twelve pairs of cranial nerves, making forty-three pairs of cerebrospinal nerves.

PHYSIOLOGY.

1. *Osmosis:* "If two different liquids are separated from each other by a porous partition, a current sets in from each liquid to the other. The strength of these currents depends on the facility with which the liquids are imbibed by the partition and the tendency the two fluids have to mix with each other; the fluid which soaks most rapidly into the partition,—*i.e.* that which wets it most readily—passes through it most rapidly. If a bladder be filled with syrup and immersed in water, the water will pass into the bladder more rapidly than the syrup passes out, and may so far raise the pressure in the interior of the bladder as to burst it. The water is said to pass into the bladder by endosmosis, and the syrup to pass out by exosmosis. Dialysis differs from osmosis in this: In dialysis a crystal loid in solution passes into a fluid, which contains a smaller quantity of the crystalloid; osmosis occurs at the same time, but the phenomena are quite distinct. The law of osmosis deals only with the currents of liquid. The blood-vessels of the alimentary canal absorb fluids by osmosis. The plasma has only a very slight tendency to pass out of the vessels, while the liquids contained in the alimentary canal pass into the blood with great readiness. The *laws of osmosis* are: (1) The liquids must be of different densities. (2) They must be capable of mixing with each other. (3) The membrane must be permeable to at least one of the liquids. (4) The current produced is greater the greater the tendency of the liquid to permeate the membrane—the greater current is spoken of as endosmosis, the lesser as exosmosis. All these conditions exist between the blood and the fluids with which the blood-vessels are surrounded, and the fluids outside the vessels pass into them more readily than the blood plasma escapes. Endosmosis usually occurs from a lower to a higher pressure."—(*Aids to Physiology.*)
2. *Urea* has the formula $CO(NH_2)_2$; it "crystallizes in transparent needles or four-sided prisms, without Aq; permanent in air; odorless, having a cooling, slightly bitter taste, resembling that of saltpeter. Soluble in an equal weight of cold water, very soluble in boiling water, and in five parts of cold or one part of hot alcohol, the solutions being neutral in reaction. At 248° F. it melts, and slightly above that temperature is decomposed. It is found in the blood, chyle, lymph, humors of the eye, saliva, perspiration, bile, milk, serous fluids, amniotic and allantoic fluids, and especially in the urine." Urea is always present in the urine, a healthy man excreting about 500 grains of urea daily. Pathologically, the amount of urea excreted may be diminished or increased, as follows: A *diminution* may be due to some condition interfering with the normal transformation of proteins in the body, as in certain chronic diseases. More frequently, however, a diminished proportion of urea in the urine is not due to a diminution in the production, but to the fact that the urea formed has not been separated by the kidneys, as in uremia and in diseases attended with dropsical effusions. Pathologically it is *increased* in the early stages of all acute febrile diseases, except when these are attended by the formation of dropsical deposits or by diarrhea; during reabsorption of dropsical fluids; in both forms of diabetes, and in chronic interstitial nephritis.

Test for urea: Evaporate a few drops of the urine on a glass slide, moisten the residue with nitric acid, allow it to crystallize; crystals of urea nitrate will be recognized under the microscope.

3. Fresh blood stains are of a bright red color, contain hemoglobin, and may show corpuscles; but after a short time of exposure (anywhere from one to five or six days) the stain becomes reddish-brown or brown, and contains hematin crystals, recognizable in solution by their spectroscopic absorption bands.
4. *Fibrin* is found in blood and lymph; *chondrin,* in cartilage and bone; *leucin,* in pancreas and spleen; *hippuric acid,* in the urine.
5. It is slowed or inhibited. (*a*) About 108 to 130 beats. (*b*) About 60 to 65 beats.
6. See Gray's "Anatomy" (1908), pages 1288 and 1330. The *purpose* is to propel the contents.
7. See Cunningham's "Anatomy" (1908), page 1062; or Gray's "Anatomy" (1908), pages 1298 to 1304, and 1326.
8. Center for *sight;* is located in the occipital lobe; for *hearing,* in the first temporal convolution; for *smell,* in the uncinate gyrus.
9. If the pancreatic duct were obstructed, there would be a decided diminution in the activity of the digestion of all kinds of foods—particularly of proteids and fats; there would be noticeable carbohydrate indigestion, and starch and fat would be abundant in the stools.
10. *The office of the Columnæ carneæ* is: To prevent too great dilatation of the ventricles; to regulate their contraction; and (through the chordæ tendineæ) to prevent the mitral and tricuspid valves from being turned into the auricles.

MATERIA MEDICA AND THERAPEUTICS.

1. Atropine.
2. Ichthyol. *Source:* A quartz containing the fossilized remains of fish. *Therapeutic uses:* Skin diseases (eczema and psoriasis), to remove inflammatory processes and their products; also in rheumatism, erysipelas, and for ulcers of the leg.
3. *Spigelia* is an anthelmintic against lumbricoid worms.
4. *Therapeutic indications for use of chloral:* As a hypnotic (in absence of pain); as an antiseptic, in a 1 per cent. solution; in cases of acute mania or delirium tremens; in nervous dyspepsia, in fevers with high temperature, excitement, restlessness, etc.; in seasickness; in tedious labor, to relax a rigid os, and for uterine inertia; for nocturnal epilepsy; for infantile convulsions, chorea, whooping cough, and laryngysmus stridulus; in tetanus and strychnine poisoning it is said to be antagonistic; as an antipruritic. *Dangers:* Habit formation; depression of body temperature; it also slows and weakens the heart, lowers blood pressure, and depresses respiration.
5. Gallic acid. *Source:* Tannic acid (from nut galls). *Dose:* 15 grains.
6. *The therapeutic uses of chromium sulphate* are of such very recent recognition that they are not even mentioned in the most modern textbooks. From the literature put out by the chemists who prepare and sell it we extract the following: The diseases in which it has been used with success are: Cirrhosis of the female breast, castration, menopause, functional impotency in men, chronic alcoholism, nervous vomiting and vomiting in pregnancy, neurasthenia, locomotor ataxia, exophthalmic goiter, and the migraines.
7. See French's "Practice of Medicine" (1907), page 149; or Osler's "Practice of Medicine" (1909), page 164.
8. *Indications for strophanthus:* As a cardiac stimulant; in mitral or aortic obstruction; in cardiac dilatation; palpitation; alcoholism; exophthalmic goiter; nephritis; when heart action is feeble but rapid, and accompanied by low arterial tension; in general, same as digitalis.
9. R. Atropinæ sulphatis, gr. 16/100.
Potassii iodidi, ℥ss.
Infusi digitalis, ℥ss.
Elixiris simplicis, q.s. ad ℥ij. M.
Sig.—One teaspoonful in water four times a day.

10. The *alkaline method in the treatment of rheumatism* consists in: The internal administration of sufficiently large doses of alkaline salts to render the urine quickly alkaline; in maintaining this alkaline reaction as long as the rheumatic symptoms continue; and in gradually allowing a neutral or acid reaction to return by gradually diminishing the alkalies as the symptoms decline. It is claimed for this method that, as the alkalies begin to exhibit their action on the system, the whole aspect of the case becomes more favorable, the general distress being alleviated, the temperature falling, and the local symptoms relieved; that these favorable effects continue to become more and more marked, until the rheumatic condition has disappeared; that the average duration of the attack is greatly shortened; and that the proportion of visceral affections is much reduced.—(From Quain's *Dictionary of Medicine.*)

CHEMISTRY AND TOXICOLOGY.

1. *"The presence of lactic acid* is detected by *Uffelmann's reagent,* which consists of a solution of Fe_2Cl_6 and phenol, diluted to an amethyst-blue color, which is changed to yellow by lactic acid. In order to avoid error by the action of other substances which have a like action upon the reagent, 10 c.c. of the filtered gastric contents are agitated with ether, and the ethereal extract separated and agitated with the reagent; or, it may be evaporated, the residue dissolved in water, and the solution added to the reagent." —(Witthaus' *Manual of Chemistry.*)

2. *Test for indican in the urine:* The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chlorid, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.

3. During the process of digestion starches are changed into glucose, which the system of the diabetic patient cannot utilize; and which, therefore, increases the percentage of glucose excreted in the urine.

4. *Test for strychnine:* Strychnine forms a colorless solution with concentrated H_2SO_4. If a crystal of potassium dichromate be drawn through this solution it is followed by a track of color which is first (for an instant) blue, then violet, then rose-colored, and finally yellow.

5. *Synthesis* is the building up of compounds from simpler compounds or from elements. *Three synthetic coal-tar products:* Acetanilid, phenacetin, and antipyrin.

6. Tannin or tannic acid is the antidote to practically all alkaloids, because it precipitates them and forms compounds (tannates) which are almost insoluble.

7. Tyrotoxicon is a ptomaine; it is found in poisonous cheese, or milk, or ice-cream.

8. In poisoning by wood alcohol: Wash out the stomach, give pilocarpine hypodermatically, and administer strychnine.

9. In poisoning by laudanum: Wash out the stomach with a 1 per cent. solution of potassium permanganate, give strychnine, keep the patient awake, and institute artificial respiration if necessary.

10. Fats and oils should not be administered in poisoning by phosphorus, because they would aid in the absorption of more of the poison.

PATHOLOGY.

1. See French's "Practice of Medicine" (1907), page 838; or Osler's "Practice of Medicine" (1909), page 571.

2.

LUPUS.	EPITHELIOMA.
Is tuberculous.	Is not tuberculous.
Comes in early life.	Comes later in life.
Is of slow growth.	Grows more rapidly.
Little or no pain.	May be very painful.
Edges and base are soft.	Edges and base are hard. Ulcer is deep, with waxy edges crossed with dilated blood-vessels.

3. See Rose and Carless' "Surgery" (1908), page 744; or Da Costa's "Surgery" (1908), page 700.

4. See French's "Practice of Medicine" (1907), page 154; or Osler's "Practice of Medicine" (1909), page 170.

5. See French's "Practice of Medicine" (1907), page 218; or Osler's "Practice of Medicine" (1909), page 210.

6. See French's "Practice of Medicine" (1907), page 523; or Osler's "Practice of Medicine" (1909), page 740.

7. In *tabes dorsalis* the posterior columns of the spinal cord and the posterior nerve roots are involved. The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus. The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

8. See French's "Practice of Medicine" (1907), pages 850 and 855; or Osler's "Practice of Medicine" (1909), page 548.

9. See French's "Practice of Medicine" (1907), page 731; or Osler's "Practice of Medicine" (1909), page 457.

10. See French's "Practice of Medicine" (1907), page 73; or Osler's "Practice of Medicine" (1909), page 68.

BACTERIOLOGY.

1. Yellow fever is caused by a specific organism not yet isolated. The *Bacillus icteroides* of Sanarelli was formerly supposed by some to be the cause. Whatever the cause, it is conveyed by a mosquito, the *Stegomyia calopus.*

The spread of yellow fever can be prevented by the use of screens and mosquito nets, by destroying the mosquitos in the house by the use of burning sulphur or pyrethrum, by draining the swamps, by remaining indoors during the hours when the mosquitos are most active.

2. To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food.

3. The bacillus of diphtheria is called the Klebs-Loeffler bacillus. *Characteristics:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly, or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

4. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue. The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length, and about one-third to one-half a mikron in breadth, is a strict parasite, is not motile, and has no flagella. It is slightly curved, does not form spores, is not liquefying, and nonchromogenic, is aërobic; it resists acids; it grows well on blood serum; stains well by Ehrlich's, Ziehl-Nielsen's, or Gabbett's method; it is Gram-positive.

5. The *Streptococcus pyogenes* is a micrococcus, of spherical shape, and arranged in chains of about thirty or forty cocci (in liquid media), but the chains are much shorter in solid media. Each coccus is about one-half to two mikrons in diameter. It is not motile, does not form spores, does not liquefy gelatin, and stains readily with the ordinary anilin dyes, and by Gram's method.

It is *found* in the mouth, nose, urethra, vagina, and on the skin; also in suppurations, erysipelas, pneumonia, pyemia, septicemia, abscesses, empyema, osteomyelitis, etc.

The *staphylococcus pyogenes aureus* is a small round cell which appears in clusters like a bunch of grapes; its diameter is about 0.8 to 1.0 mikron; it is facultative anërobic, has no flagella, is not motile, it stains readily with

the anilin dyes, and is not decolorized by Gram's method; it forms an orange pigment on gelatin, potatoes, and other media; it also liquefies gelatin. It is *found* on the skin; in the nose, mouth, ears, and eyes, and under the nails; also in abscesses, boils, carbuncles, osteomyelitis, arthritis, empyema, and suppurative inflammations in general.

6. *Antitoxins* are substances formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

Immunization is an experimental process by which the resisting powers may be increased.

7. *The Noguchi method of the serum diagnosis of syphilis* is a modification of the Wassermann reaction. This latter Noguchi modifies as follows: "(1) He prepares the antigen by extracting a lipoid substance from the liver and heart of dogs and cows. (2) Instead of using sheep's corpuscles in the hemolytic series, he employs human corpuscles, owing to the fact that a certain percentage of human sera tested produced hemolysis of the sheep's corpuscles. (3) In his test, therefore, he obtains the hemolytic amboceptor by immunizing rabbits with washed normal human corpuscles. (4) Another important improvement in the technique is the preservation of the specific antigen and the hemolytic amboceptor, which rapidly lose their strength in solution, in a dried form by soaking measured strips of filter-paper (.5 mm. square) with each. His test is carried out as follows: A strip of antigen filter-paper is brought in contact with a definite quantity of the human serum to be tested and fresh guinea-pig's serum added, the whole being suspended in isotonic salt solution. This is allowed to stand at incubator temperature and then the hemolytic series added by taking a strip of the hemolytic amboceptor paper and a definite quantity of washed normal human blood corpuscles."—(Tyson's *Practice of Medicine.*)

8. "Tetanus antitoxin is obtained from the horse, the animal having been rendered artificially immune by repeated injections extending over a period of several months of gradually increasing quantities of the strongest tetanus toxin. As the bacilli themselves are not injected, the horse does not become infected with tetanus, but he gradually acquires a tolerance for the toxins of the disease and develops in his blood a substance (antitoxin) which has the power to neutralize those toxins. At the proper time, when it is thought that his blood has acquired the requisite degree of potency, the animal is bled, and the serum—the part of the blood containing the antitoxin—is carefully separated from the clot, filtered, and standardized. The last procedure is accomplished by determining the quantity of antitoxin serum required to offset the effects of the minimum quantity of toxin necessary to kill a guinea-pig in a definite time. The strength of the antitoxin is measured in units, a unit containing the amount of antitoxin required to save the life of a guinea-pig which has been injected with 100 fatal doses of toxin."—(Stevens' *Materia Medica.*)

How antitoxin produces immunity and effects cure is not known, but *theories* deduced from observed facts are as follows: "As the various pathogenic bacteria produce the causative toxins of their respective diseases, so the organic cells of the body, reacting under the stimulus of the poisons thus introduced, immediately proceed to elaborate defensive bodies, which if produced in sufficient quantity will neutralize the effects of the toxins. Residual antibodies remaining in the blood after recovery render the animal immune for a time against the disease. The immunizing and curative effects obtained by the injection of the blood serum of an immunized animal into the circulation of another animal are due either to direct chemical neutralization of the toxins themselves by the antibodies so introduced (Behring, Kitasato), or to a particular influence exerted by the antibodies upon the living cells of the organism which, being affected in two opposite directions, remain neutral to the disease (Buchner). Some authorities hold that these results are due to the conjoint action of leucytic and chemical forces. Ehrlich's sidechain theory assumes that every toxin contains toxophore molecules having direct toxic action, and haptophore molecules which combine the toxophores with a similar combining group of molecules in the tissue cell of the attacked organism. The tissue cell molecules being destroyed by the toxophores, a rapid and profuse regeneration of similar molecules occurs in side chains, and these molecules overgrowing are carried into the circulation, becoming the antitoxin, which acts by combining with the haptophores of newly-arrived toxin, using up their combining power before they can reach the tissue cells."—(Potter's *Materia Medica*, etc.)

9. *Streptothrix actinomyces* appears in the form of branching threads which interlace with each other. The external ends may be rounded or bulbous. Colonies of them have a radiating appearance, and so have been called ray-fungus. It stains with ordinary anilin dyes, and is Gram positive. It is facultative anerobic, non-motile, non-flagellate, parasitic, and pathogenic.

10. *Gram's method of staining:* Stain a cover glass preparation for two or three minutes in anilin gentian-violet. Wash in water. Treat with Gram's solution (iodine, 1 gram; potassium iodide, 2 grams; water, 300 c.c.) for a minute and a half, when the preparation becomes nearly black. Decolorize with strong or absolute alcohol for at least five minutes, wash, dry, and mount. Sometimes a contrast stain of Bismarck brown or eosin is used.

PRACTICE.

1. See French's "Practice of Medicine" (1907), page 7.

2. See French's "Practice of Medicine" (1907), page 599; or Osler's "Practice of Medicine" (1909), page 820.

3. See French's "Practice of Medicine" (1907), page 103; or Osler's "Practice of Medicine" (1909), page 95.

4. See French's "Practice of Medicine" (1907), page 326; or Osler's "Practice of Medicine" (1909), page 141.

5. See French's "Practice of Medicine" (1907), page 685; or Osler's "Practice of Medicine" (1909), page 641.

6. See French's "Practice of Medicine" (1907), page 1039; or Osler's "Practice of Medicine" (1909), page 902.

7. See French's "Practice of Medicine" (1907), page 1100; or Osler's "Practice of Medicine" (1909), page 989.

8. See French's "Practice of Medicine" (1907), pages 695, 698, and 685; or Osler's "Practice of Medicine" (1909), pages 649 and 641.

9. *The ophthalmoscope would aid in the diagnosis of:* Brain tumors, abscesses of brain, anemia of brain, cerebral aneurysm, tabes dorsalis, multiple sclerosis, exophthalmic goiter, nephritis, diabetes, hypertrophy of the left ventricles of the heart, fatty degeneration of the heart, syphilis, alcoholic or tobacco poisoning.

10. See French's "Practice of Medicine" (1907), page 647; or Osler's "Practice of Medicine" (1909), page 598.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 147; or Hirst's "Obstetrics" (1909), page 91.

2. Veit's figures, based on 13,000,000 cases, show that twins occurred once in 89, and triplets once in 7,910 labors.

3 and 4. See Williams' "Obstetrics" (1909), page 599; or Hirst's "Obstetrics" (1909), page 155.

5. See Williams' "Obstetrics" (1909), page 619; or Hirst's "Obstetrics" (1909), page 281.

6 and 7. See Williams' "Obstetrics" (1909), page 280; or Hirst's "Obstetrics" (1909), page 414.

8. See Williams' "Obstetrics" (1909), page 821; or Hirst's "Obstetrics" (1909), page 587.

9 and 10. See Williams' "Obstetrics" (1909), page 843; or Hirst's "Obstetrics" (1909), page 626. The position recommended is the Trendelenburg.

SURGERY.

1. Anastomosis after ligation of femoral artery at apex of Scarpa's triangle: (1) External circumflex; with muscular branches of femoral, anastomotica magna, superior articular of popliteal, and anterior tibial recurrent. (2) Perforating and terminal of profunda; with muscular branches of femoral, and muscular and superior articular branches of popliteal. (3) Comes nervi ischiadici; with perforating of profunda and articular of popliteal.

2. *Paracentesis thoracis is preferably performed:* "In the fifth interspace, just in front of the angle of the scapula" (Da Costa). "Sixth (or seventh) intercostal space in the midaxillary line; eighth (or ninth, especially on left) intercostal space in the posterior scapular line" (Bickham).

3. See Rose and Carless' "Surgery" (1908), page 208; or Da Costa's "Surgery" (1908), page 328. *Treatment* consists in removal.

4. Carcinoma is disseminated through the lymphatics chiefly, also by the blood, and occasionally by mechanical transportation in the movements of the body.

5. The swelling and fluctuation are most prominent on either side of each malleolus, and also in front.

6. See Rose and Carless' "Surgery" (1908), page 115; or Da Costa's "Surgery" (1908), page 1052.

7. *Excision of the lower jaw is advisable* in: Various tumors of that bone (chiefly malignant), and also in extensive necrosis.

8. *The complications of dislocation of the hip* are: Extensive injury to the soft parts (such as rupture or lacera-

tions of the muscles); rupture of, or dangerous pressure on, the femoral vessels or sciatic nerve; fracture of the head, neck, or shaft of the femur, or of the acetabulum.

9. *Varieties of shoulder joint dislocation:* (1) Subcoracoid—forward, inward, and downward. (2) Subglenoid—downward, forward, and in ward. (3) Subspinous—backward, inward, and downward. (4) Subclavicular—forward, inward, and upward.

10. See Rose and Carless' "Surgery" (1908), page 383; or Da Costa's "Surgery" (1908), pages 680 to 684.

GENITOURINARY AND DERMATOLOGY.

1. See Rose and Carless' "Surgery" (1908), page 1159; or Da Costa's "Surgery" (1908), page 1101.

2. See Rose and Carless' "Surgery" (1908), page 142.

3. *Hydrocele* is a collection of fluid other than pus or blood in the neighborhood of the testis or spermatic cord, generally in the tunica vaginalis of the testis. For operations see Rose and Carless' "Surgery" (1908), page 1267; or Da Costa's "Surgery" (1908), page 1201.

4. See Rose and Carless' "Surgery" (1908), pages 142 to 162; or Da Costa's "Surgery" (1908), pages 274 to 296.

5. *Symptoms of stone in the bladder:* Increased frequency of micturition; pain at end of urination, chiefly felt at the end of the penis or in the neck of the bladder; the urine may contain pus, mucus, or blood; a "click" can be obtained by using a searcher or sound; examination by the cystoscope may reveal the presence of the stone.

6. *Common sites of epitheliomata:* Nose, lower lip, tongue, mouth, larynx, esophagus, stomach, anus, larynx, penis, scrotum, vulva, cervix uteri.

7. *Xanthoma* is a disease in which a yellow or brownish discoloration appears about the eyelids and other parts of the body. The discoloration may be flat, or papular, or nodular.

8. Keloid. *Cause* is not known; the negro race is prone to the disease; there may be some minute injury preceding the disease. *Treatment:* Removal is useless, as it may return; scarification has been recommended; the *x*-ray has proved beneficial; violent methods should be avoided; it may disappear spontaneously.

9. Bromidrosis. *Causes:* Unknown; racial peculiarity, as in the negro; it has been attributed to decomposition of the sweat; also to a parasite, a bacterium. *Symptoms:* Offensive odor to the perspiration, most often affecting the feet or axillæ. *Treatment:* Not much use; washing of the affected part with soap and water several times a day and putting on of clean cloths; various dusting powders. Generally ineffective.

10. Pompholyx. *Causes:* "It occurs in adults of both sexes, and is believed to depend upon some general disturbance of the nervous system. Mental overwork and lowered nerve-tone are ascribed as causes. The disease is considered to be a vasomotor neurosis. *Symptoms:* The lesions are distributed symmetrically, and occur as deep-seated, tense vesicles usually on the lateral and palmar aspects of the hands, fingers, feet, and toes, accompanied by itching and burning. They may coalesce, but more frequently they remain discrete, showing no tendency to rupture. The contents are absorbed and desquamation follows. The duration of the attack is from several days to a few weeks. Recurrence is common. *Treatment:* Recurrence may be prevented to a great extent by the employment of measures calculated to improve the general health. Locally, pastes, ointments, or lotions containing antipruritic drugs often allay the subjective symptoms."—(Hughes.)

Trichocephaliasis and Trichocephaloanemia.—Guido Guidi makes observations on the frequency of trichocephaliasis in children, and shows that it results, in the long run, in a marked form of anemia. Although innocuous in the majority of the cases, in some individuals it brings about morbid states that are marked, represented by alterations in the blood, and severe anemia. This anemia is of simple type, and is found, chiefly, in children. It is due to loss of blood by means of ulcerations produced in the intestine, alterations in the process of digestion and absorption, and absorption of toxic products of the life of the parasite. Infection occurs by water, by eating materials which have been watered with sewage, and by contact of the hands with materials containing the parasites. There is general weakness, vertigo, headache, diarrhea, intestinal hemorrhages, vomiting, pain in the abdomen, and fever. In the blood there is lowering of hemoglobin, hypoglobulia, poikilocytosis, macrocytemia, and microcytemia, nucleated red blood cells, oligochromemia, diminished globular value, leucocytosis, and possibly eosinophilia.—*Ricista di Clinica Pediatrica.*

HYSTERIA UNDER PSYCHOANALYSIS.

By GEORGE M. PARKER, M.D.,

NEW YORK.

ATTENDING PHYSICIAN ROOSEVELT HOSPITAL, O. P. D. DEPARTMENT OF NERVOUS AND MENTAL DISEASES.

Psychoanalysis, as a procedure, is showing a sharp growth curve in this country after a very considerable incubation period. True to its native history and traditions, it is likewise developing a marked capacity for making warm friends and bitter enemies. We find it both over-exalted and under-estimated, proclaimed as the most efficient instrument known to modern neurology and psychiatry, and derided as a complicated revamping of medical folklore. With the enthusiast, it assimilates facts in the avid manner of a Shandian hypothesis; for the obstructionist, not even the alleged similitude to old and intimate measures serves to temper the bitterness of its rejection.

While some degree of oscillation must precede the arrival at a balance, a part of this too considerable divergence should be possible of elimination. A consideration of its history, the psychological essentials, the type of mechanism, and the application to definite clinical groups should serve to give a fair valuation to it, provided always there be the intent towards defining its relation to the acquired knowledge and facts that have preceded it. The necessity of limiting the scope of such an inquiry has led to making hysteria the chief consideration of this paper as seen in the light of psychoanalysis.

In the beginning, psychoanalysis as an isolated organized method did not exist. It grew from an effort at reducing certain neuroses to their psychological fundamentals. Because of this concealed origin, thus implicitly expressed, many have failed to credit the real beginning with Janet at the Salpetriere, rather fixing the point of origin at another and later point where the procedure was more explicitly stated. Hysteria served Janet as a stalking horse. His work with Charcot had raised him in the fullest hysteria clinic of Europe. The advanced work here in hypnosis had made for a more close and intelligent analogical rapport. Back of this was a strong psychological bent and training. The manifestations of hysteria he based upon a narrowing of consciousness, not so much the epiphenomenon, a name for the function of the mind, as the content of consciousness. The tendency toward this constituted the chief criterion of hysteria. The producing factor of this split was psychogenic. The resultant was a dissociated constituent of the stream of consciousness, which, becoming subconscious, integrated and grew to different degrees of organization, its potentiality being in direct ratio to this growth. The various manifestations, sensory, motor, and psychic, were due to the action of this subconscious focus upon the stream of consciousness, depending upon the degree of interference produced by its partial or complete reappearance, thus destroying the continuity of normal reactions. These upheavals were viewed as due either to direct growth in focus or to transitory states where the consciousness was tenuous or reduced.

This makes up the formula of hysteria for Janet as developed in his "Mental State of Hysterics and Neuroses and Fixed Ideas." Its essential constituents are the psychogenic cause, the dissociating mechanism, the organization of the dissociated content with its operation upon the stream of consciousness. Its application was made specifically to hysteria. Close attention to these concepts reveal certain lacunæ. It is necessary to go over these gaps, for they show the origin of later extensions which have, perhaps, overshadowed the original work of the French psychologist. Janet, made of the psychogenic factor a massive, vivid, sensory impression of tremendous emotional tone acting as a psychic shock in narrowing and obliterating the stream. The sheer impact from without made the break. The concept was thus limited to an exceedingly narrow range, for not only gradations of intensity were inoperative until that point had been arrived at where the dissociation occurred, but, also, only factors operating directly and immediately from without were here established. This is the first limitation giving opportunity for subsequent development. Dissociation as a mechanism has never been more clearly shown in careful psychological terms than by Janet. He was the first to exemplify it in a constructive and clinical manner. Yet it was only one type of dissociation, requiring for its production the peculiar kind of psychogenic factor described above. In its operation the break in continuity was immediate and complete; the criterion was loss of content, demonstrated by amnesia. The content was the isolated block of personal experiences made up by the factors of the shock with its sensory and emotional accompaniments. The lines of severance at the beginning and end were clearly cut. Despite the perfection of analysis in this complete type of dissociation, Janet took no account of gradations in this process beyond a certain difference in depth of dissociation as applied to the sensory or emotional constituents of a given experience. By gradations is here implied not only gradations of intensity but gradations in a time sense of a dissociation gradually occurring through repeated minimal dissociations. It is quite reasonable to assume that such would be more frequent than the extreme type, provided the mechanism were proved as fully operative in one as in the other. The second gap is at this point. The organization of the

dissociated focus and its operation upon the stream of consciousness may be considered as the third division of Janet's work. This is acute and explanatory; the methods of demonstration are ingenious, the reasoning sound, the dissociated content, proven as existent, at a lower level, is shown to possess possibilities of organization. To effect this, the nucleus must have the power of absorbing other stuff to itself, in this implying further dissociation. This absorption and organization may proceed to a formation of that which is carelessly called a secondary personality. Always there is a tendency towards this organization; equally constant, the dissociated experience remains the plainly traceable focus. The operation of this dissociated and more or less organized state is due to a tendency to rise towards normal levels in a quasi-automatic manner as a repair of synthesis, this movement being favored by any conditions making for a temporary limitation or weakening of the stream of consciousness. To this Janet traced a large proportion of the major manifestations. The intruding content bears the character of the reproduced, reinstated fragment, yet failing to fuse at this upper level, because, through this act of intrusion, the material possible to fuse with has been displaced and all associative bonds blocked. Until this fusion occurs, the tendency towards it persists. In this section one meets a strict, almost mechanical association concept. It presents less of gaps than alternatives. The constantly identifiable presence of a focus, the persistent organization solely through absorption, the interference with consciousness through an associative tropism seen in the inherent tendency towards reinstatement and resynthesis, all these lines, however sound psychologically, are not sufficient as a universal explaining mechanism. Therapeusis, the sum of these three terms, rests with a recovery and resynthesis of the dissociated content. Hypnosis is employed as a means to arrive at the lost material which, in this state, tends to rise spontaneously. With the resulting hypermnesia the entire subconscious organization is rapidly brought up. Amnesia disappears *pari passu* with the successive emergences. Further alterations and suggestions are possible to effect with unduly persistent pathological elements. The procedure stands close to a literal reconstitution of the stream of consciousness. Despite these gaps, the work of Janet in hysteria has furnished the soundest material for subsequent investigators as affording the first clear clinical and thorough psychological concept of dissociation. An acquaintance with it is necessary for a proper understanding of the work of men now more conspicuous in this field.

Freud's contributions now stand as the most important. While judged on their own peculiar merits they will yet, in part, be viewed by the light of that which has preceded with the purpose of revealing their similarities and divergences. As with Janet, hysteria was the subject of Freud's initial work. Unlike Janet, he has come to extend it immeasurably beyond these limits. With Freud, moreover, it will be seen that there was infused a philosophic leaning foreign to Janet, a tendency possessed of certain advantages and definite dangers. In 1893 a preliminary communication came out, followed in 1896 by his "Studienuber Hysteria" in conjunction with Breuer. The concepts in this work formed the basis for further extensions in his "Traumdeutung and Psychologie des Alltagsleben." In this order they should be read if one desires to follow the progressive evolution of these ideas. Freud asserted the psychogenic factor. Its action upon consciousness he described as due to insufficient reaction emotionally and intellectually. There was no distinct, clear-cut break of a dissociative character. To meet this he conceived the mechanism termed exclusion, meaning by this the voluntary and persistent putting away by self of the memory of the factor. The result would be a gradual dislodgment, and displacement from consciousness of the experience. The displaced experience is peculiar as to content, organization, and function. Its content always holds an element of an unfulfilled desire, which implies a conative direction; its organization is not one in the sense of an integration but a stringing of associations of diverse type and irregular formation, each rigidly deterministic as to its immediate successor, generalized under several broad groups; its function is displayed by an interference with consciousness as an intruding or foreign element under conditions where the excluding mechanism is not efficient for the moment in maintaining its function.

The amplification of this bare formula of Freud's will show greater differences than appear in its abstracted form, the points of divergence coinciding largely with the so-called gaps noted in Janet's. Freud's first point in regard to the psychogenic factor is important and constitutes a definite departure from Janet. The content of the initial impression is made sexual, explicitly or implicitly. In the beginning, he formed this basis apparently from a posteriori grounds but the sharp attacks directed at him have driven him to apriori territory, where his position is less secure. Despite this, his defining of the sexual nucleus, his ingenious demonstration of its efficacy in producing diverse results makes his attempt at formulating a unity of causation a distinct advance upon Janet who held that the content might be varied so long as it possessed a potentiality for producing cleavage. He insisted upon the massiveness of the shock, that it should be sufficient to make a clean-cut dissociation with subsequent submergence and amnesia. Freud here followed another line. He held that an immediate dissociation was not necessary to postulate, but only that the impression be not reacted to, that it be not assimilated, balanced, and equalized. While this means an incomplete association, it does not imply or necessitate a strict dissociation. His next step served to amplify this conception. He sought to show that not only was it unnecessary to claim an immediate and complete dissociation, but that there was to be found a mechanism capable of producing a similar end result through a different process. This is accomplished by his "exclusion," paired with its resultant, the "displacement or dislodgement." He understands by the exclusion a quasipsychologic function called by him the "censor." We have intimate knowledge of its acting at every moment when we try to push away from our attention or memory unpleasant facts, recollections, yearnings. We quite persistently and habitually thus censor our immediate mind stuff. Now this mechanism forms an important link in the series of Freud's concepts. With the sex factor it finds a connection in the established fact that pedagogy, training, morals, and life have taught and enforced the exclusion of this nucleus more than any other. The next

link to which it is connected is the peculiar character of the excluded content. Freud sees this generalized under the type of an unfulfilled desire. With sexual attraction as the most powerful conative end, persistently functioning because unfulfilled, it makes plain the reason for the necessity of continuous operation in this exclusion mechanism. This constant exclusion of the recurring nucleus finally leads to a dislodgement, or displacement. This important factor deserves a close attention in its comparison with Janet's. As a psychological mechanism, its function is widely different. It implies volition, a constant, conscious effort, varying in efficiency and success, necessitating, at times, a tremendous outlay of energy with its successive fatigue; or it issues in a partial failure, leaving as fruit certain curious, mental compromises. It affects personality as the extra-personal shock cannot. The end results of this mechanism may be compared but should not be confused with Janet's. Here a definite group of psychic elements, an experience, drops *en bloc* from the stream of consciousness. Freud makes this gradual, the result of constant, volitional exclusion, so that the displaced fragment fails to represent the clean-cut, limited group of Janet, but possesses a character radically different. The excluded and subsequently dislodged content is not simply the stuff toward which the exclusion was primarily directed, either in material or form. It has undergone changes, contamination, substitutions, losses, or additions. The manner of its production through repeated exclusions makes this. Nor is the criterion of its dislodgement that definite amnesia obtaining with Janet's dissociation. Yet viewed as end results alone, both are dissociations; viewed in the manner of their respective mechanism or function, they are so different that a definite originality must be granted Freud's concept. Further differences, issuing from these, are seen in the effect upon consciousness and personality. The underlying motif in this part of his conception is the unfulfilled desire, while with Janet it remained the persistent striving at a resynthesis of the dissociated fragment, all the various clinical phenomena being made dependent upon this initial dissociation and those added to it as the growth of the nucleus persisted. Freud avoids this organization idea. Through a host of varied associations, he sees the unfulfilled desire moving, always determining its immediate successor, suffering continuous alterations through each repeated exclusion, rarely or never presenting the isolated fragment originally excluded, contaminating innocent associations with its affective tone, under this cloak reappearing as an obsession, unexplainable to the patient, or represented by symbols, appearing in dreams or as bizarre sensations and visualizations, undergoing conversion into a blind range of somatic symptoms, extending into irregular delusional formations, capable of these and a thousand other mutations without loss of real continuity. Freud's therapeusis is simple to express. Kathersis—he calls it; a reaction, incomplete at time of a given impression, later constantly excluded, is made complete by a retracing through all its varied manifestations and by its thorough expansion before the patient. It is thus reduced to proper proportions, assigned to its peculiar place, and handled in an adequate and normal manner through this regained and reinforced reaction. Not a word about synthesis here, yet what has been just described is its highest form. Nor does any trace of suggestive work appear. In the long process of equalization, expansion, and alteration, this must function, but equally well it may be subsumed differently with no damage to the facts. It is unnecessary to do more than indicate these merely nominalistic differences which exist side by side with other marks distinctive and distinguishable in the two series.

This comparison of the work of Janet and Freud has two purposes. It is directed first toward displaying the psychological essentials of both series with their respective limitations and excellencies. Also, because a recent work always gains in illumination through even a remote and fainter light, it has been felt that Freud's theories might show an added definition through the clean-cut psychological concepts of Janet, while, conversely, the demonstration of the gaps in the latter's work should give a better valuation to the important extensions originating with the former. The second purpose is more practical. It is to show that neither theory is absolutely inclusive; that each in displaying peculiar excellencies and defects should reveal a varied range of adaptation for correspondingly varied groups. This difference in clinical adaptability is obviously important, especially as it may lead toward a more intelligent selection of method for theapeutic purposes.

In introducing the clinical section, one reservation is to be made. The pursuit of as strict a comparison here as in the psychological section would confine the cases to hysteria, for to this field Janet's work in dissociation was limited. Because a peculiar virtue of Freud's work rests in its extension to other neuroses, it would be unfair to limit the range here to hysteria without acknowledging this gap made necessary by the desire to get some clinical unity out of the paper. The cases making up this section were largely drawn from the Department for Nervous and Mental Disease in the Roosevelt Hospital O. P. D., that they may serve as a latent argument for the practicability of the work under conditions much less favorable than those possible in private practice. The first case presented, however, is abstracted from an article by the present writer in the *Boston Medical and Surgical Journal* (Aug. 31-Sept. 7, 1906).

Case I.—The patient had a good family history. Her own life had been normal up to the time of her trouble except for the incident of overwork in school. The mental state for which she was placed under observation dated back one year. At this time she had experienced a peculiar shock. A report was abruptly broken to her by an excited neighbor that a brother had been decapitated by a passing train. A book she had been reading dropped; she appeared as though about to faint but rallied. The news was changed presently by a verification of the accident not to her brother but to a friend of his living with them. In the evening, upon the homecoming of the father, the incident was recited to him. The patient appeared distressed, picked up a book to read and fell unconscious; after one-half hour she recovered with total amnesia, both of the occurrence and the news of the morning. The next day a similar attack followed the shrill whistling of a locomotive. Incidents of the funeral precipitated a third. The amnesia persisted. Her environment was changed but with no deterring effect upon the attacks which rather increased. Soon the amnesia became retro-

active. Isolated instances at first dropped; later entire blocks of her life disappeared. A more radical environmental change was advised to avoid all old associations. The state advanced; attacks became more frequent ensuing upon any light distractive conditions. The amnesia became more continuous. Automatisms were numerous, extending up to very considerable fugues. Dream life was filled with the lost content but upon awakening not recognized by her as such. The affective state became one of acute apprehension with a marked depression. Her grasp deteriorated, and the attention weakened, the general picture giving one the impression of an approaching psychosis. Psychoanalysis began with the production of light hypnosis. This opened up the mechanism with considerable clearness. The book held by her at the time of the shock had upon its cover an intaglio head. This had fused with her representation of the decapitated head of her brother and immediately had been dissociated. But the dissociation stopped then until again the same book was picked up in the evening when the first complete attack ensued with the subsequent complete amnesia. This amnesic content was completely recovered with a few prolonged treatments. It showed a remarkable organization. The dream content was revived, displaying a growth extending from the sensory elements of the shock into a vast amount of stuff accruing from the amnesic content. The resynthesis was completed rapidly. The patient entirely recovered and an interval of four years has seen no reappearance of trouble.

This is a clear example of the mechanism described by Janet. There is the massive shock, the immediate dissociation with a clean line of cleavage, the dropping of an experiential block below the threshold, an organization showing within two weeks, intrusion of the content evident from the first and increasing in frequency and duration in direct ratio to the organization, these intrusions or upheavals above the threshold being dependent either upon an associative bond or upon states wherein the stream of consciousness showed weakening or attenuation and, finally, the cure issuing from the completed resynthesis obtained by the line of therapeusis. As against Freud's scheme, the impression had no sexual bonds; the dissociation followed the impact of the shock through its intensive effect, nothing even dimly comparable to an exclusion being seen; the dissociated material was clean, uncontaminated, and in its reproduction reversed the direction of the dissociation, showing that the absorption of material by the focus had followed general laws of memory. Its growth had come thus and not through the direction of an unfulfilled desire; its reappearance, constituting the attacks, had been due to the strength of the associative tropism not to the functioning of an unfulfilled complex. It stands, thus, as an example of that which one might call the type of direct, immediate dissociation.

Case II.—The family history was not obtainable. The early life was scantily described as "nervous." During her married life she has been irritable and variable in her moods. She has had "nervous" attacks sufficiently marked to require medical attention. It is not possible to define these further as the entire emphasis is laid upon later occurrences. One year ago, while in a hospital preparing for curettage, she had a "fainting" attack with three similar following within five days. The operation was postponed. Since then she has had one every two months. The attack is described as beginning with epigastric pressure, stiffening of back, bending backwards, choking sensation with production of weird noises, anesthesia of the left side, and some irregular twitching of feet and hands. The duration is about ten minutes and the post state is that of moderate delirium with hallucinosis. Amnesia follows. Aside from these attacks the general state has been changing; there are distracted episodes wherein she loses herself for a few moments, brief confusional attacks, occasional hallucinations, temporary amblyopia, a desultory amnesia, sleep filled with dreams colored by frightful content of injury toward herself, a general sense of depression with striking emotional expressions, and a lessened fitness for work.

On examination there are found anesthetic areas irregularly distributed over the entire body, analgesia is present but limited; there are marked visual limitation and slight contractures of left leg, reducible under distraction. She is ego-centric in every reaction, suggestible with marked emotional fluctuations and decided mannerisms of dramatic type; depression is exaggerated in its description and exhibition; distractive states are frequent and unmistakable with brief confusion upon emergence. There is no disturbance in stream of thought beyond such as are traceable to these episodes of distraction.

Psychoanalysis through hypnosis opened up a shock occuring eighteen months previous to admission. She had been riding upon one of the attenuated horse cars of the East Side when it was struck by an automobile. She had seen the machine approaching, rose to her feet as it struck the car, was thrown to the floor by the impact; she fainted and a zealous policeman poured down her throat some whiskey of the neighborhood quite effectually choking her, she screamed, fainted again, became delirious, was removed to the station house and held until a late hour for identification as not for several hours was she able to give her name and address. The result was amnesia as to the entire occurrence up to the time of her father arriving at the station to take her home. One month later, while in a ferryboat making a poor landing, the crash of the boat against the piers broke some glass, threw the passengers about, and brought on a second attack, less severe and more brief. Both these had become dissociated and were reinstated *en bloc* under hypnosis with a tremendous emotional accompaniment. The content of a considerable number of subsequent attacks were uncovered and demonstrated a causal connection through associative bonds issuing from the initial shock. Aside from these, however, there was evidence of considerable contamination in this content; it failed to display the organization seen in the first case; the raising of the apparent subconscious focus did not bring with it a firmly woven texture but rather one with many gaps and variegated with elements not apparently associated with other content. The subsequent clinical picture gives a transposed picture of this. Two months later she reported no further attacks, still very brief confusional moments, but no further hallucinosis nor delirium states. The anesthesia and contraction had largely disappeared. She was still raw upon the accident complex but there was no abnormal reaction upon the mention of it. Again in two months the last report showed

an improved balance, less emotional variation as applied to representation of attack, a decided gain in memory, greater fitness and but few distractive periods. A few elements of the original experience still reappear in dream state but she is no longer amnesic of them. Sensory disturbances have not reappeared. This is not the clearly finished case of the preceding type and, because of this, it has a comparative value. The criterion of this difference does not rest upon the greater duration, although in this group that fact is significant, but it rests rather upon evidence that minor dissociations were still recurring at last report. Yet in a way, it is grouped under the direct and immediate dissociation. The accident had all the factors necessary to produce the break, which was demonstrated by the definite recovery of content under hypnosis. The significant parts lie beyond this. Although the attacks were much less frequent than in case I, with each revived by similar methods, yet there failed to show any continuity in the dissociated content, any organization aside from elements derived from the shock. The supply was scanty; it did not emerge in the way characteristic of the tapping of a genuine source nor was there any true hypermnesia during the intervals. Some dissociated stuff was still retained and that it functioned was made plain by the continuation of a minor train of symptoms. The presumption arising from these facts is that the accident was not the original focus but one superimposed upon a dissociative process which had existed for a long time previous, as the scanty early history seemed to show clinically. This fundamental disturbance had not been got at by the procedure described. Freud's method would have here been employed, had not the case dropped out because of the relative improvement of the state. It will be seen in a later case that the probability of success in arriving at the real solution would have been considerable. Despite the unsatisfactory ending, the case is of real value clinically. It shows the limit of the direct and immediate dissociations. These may occur in any given case and their complete reproduction is of decided help not only in more speedily arriving at more normal reactions but in clearing away the field for finer analytic work. The important point, however, is that unless one finds the full term of Janet's type, psychogenic factor and dissociation and, in particular, organization, then the case is not a complete one of that type and demands further analysis.

Case III.—The family history was not obtainable. In her early years she had been described as a "nervous" child, easily frightened, shy, retiring, uneasy, and disquieted outside of familiar environment; the progress in school was slow. These qualities led to considerable limitation and isolation later in life. Six months ago she had a "fainting" attack from which she emerged in a state of acute fright with a marked tremor in the right hand and arm. Amnesia from attack showed. The tremor persisted; at times it would become especially violent, at such occasions producing acute agitation and in itself constituting an attack but without loss of consciousness. Twice there had been definite delirium episodes with hallucination of black men threatening her. Confusional states became common; amnesia showed frequently. Sleep was invaded with dreams of fire, burglars, negroes killing men but no sex content. Hypnogogic hallucinations were regularly present. She has been driven from work because of increasing unfitness.

Examination—There were no sensory disturbances but an extensive coarse tremor of right hand and arm, ceasing upon distraction, exaggerated readily by suggestion to a point where the entire body was shaken, slight visual limitation. The general make-up was that of a moderate inferior. She showed some depression not acute but anxious, passed readily from this to a more pleasant tone; was highly suggestible; no distractive periods were evident but attention was defective and the grasp was slow yet not due to distinctive mental defect but to an agitation which followed any question directed at her.

The psychoanalysis with hypnosis opened into a dream content with sharp reaction on the part of the patient. A black man was chasing her, his hands bloody, his aspect threatening; he caught her apron in his hands, she threw him off and her right hand in falling to her side was smeared with blood from the imprint of his fingers. She had awakened from her sleep at this point trembling and remembering nothing of her dream. The same dream had repeated itself the following night. The next day she had the initial attack as she was picking up her apron to tie about herself. The content of the attack was recovered as identical with that of the dream. The delirium episodes had back of them this general content. The tremor had persisted, however, with no relationship except to the dream. With this was an unpleasant affective tone of acute fear. The immediate effect of the procedure was to diminish abruptly the extensive range of the tremor but the confusional state and the desultory amnesia persisted with a less violent depressive tone.

From the basis of the dream there now extended lines reaching towards other elements present but undeveloped in the dream complex. The first led to an assault she had unwillingly witnessed of a colored elevator man upon a white boy, the latter being left severely wounded and bleeding. The patient was in the elevator at the time and could not get out. She was too frightened to scream and had to remain and be taken up to her floor by the assailant. The incident was so fearful that she tried to forget it. Extensions from here showed that the latter exclusion of these by her always intensified the tremor; she felt confused, dizzy, and uncertain of herself at these times. A second line ended in an early sex experience, not dissociated, but excluded and fused with the apron factor. The effect of the latter work was to complete the case. The patient went back to her tasks and report shows continued efficiency.

This case demonstrates more amply than the preceding the existence of both mechanisms, but with a distinction in the greater preponderance of the type described by Freud. The elevator experience had not operated as did the street-car accident. There was no direct and immediate dissociation; rather it was a matter of insufficient, restricted reaction with the later exclusions partly described by the patient. The dream states were the more deeply dissociated and raw and hyperesthetic. Moreover, into these converged the other lines. Hence they appeared under the artificial working of hypnosis as the most immediate and potential subconscious foci. Yet the analysis thus proceeding was not sufficient. Here Freud's method without hypnosis worked. It demonstrated the exclusion phenomena with subsequent displacement, the sex factor, the operation of these in the production of the varied symptoms of tremor, confusion, amnesia, halluci-

nation, etc. There failed only the unfulfilled desire. This would probably have appeared had the sex content been more persistenly pursued. At this very point, however, the case is perhaps the more instructive as it minimizes the need for the over-amplification of a factor which is Freud's chief sustaining ground for the fulfillment conception. The case stands then as one of indirect dissociative type in which the methods applicable to the direct show a lessened and accessory value.

Case IV.—The family history shows some inequality on the maternal side. The personal history gives the picture of a shy, fearful, unsocial child; school progress was normal, the family relations were harsh and unpleasant, yet she was efficient in her work outside of her home. For the past two years she has been less well although able to work; yet it was impossible for her to define the state further until one year ago. At that time she had her first attack, with falling down, rigidity of the left side, some spasm, and partial loss of consciousness. The duration was three minutes; there was no post-stupor but only a great fear and apprehension which also had shown during attack. Since then the attacks have occurred frequently, ranging from once in two weeks to several in a day. The general character remains the same. The prodromes are headache, a state of anxiety, disturbances of sensation over the left side, occasional hallucinations, and brief confusions. At times the attack is general with complete loss of consciousness or, again, only the stiffening may present for a moment or sudden dizziness with confusion or distractive periods arising from an attempt at persistent attention. When coming at night, they are usually preceded by dreams of which she is partly amnesic but from which an unpleasant tone proceeds. Hypnogogic hallucinations are frequent. Anesthesias, analgesias, tremors, and contractures present, rarely, however, independently of one of the varied types of attacks. Sleep is constantly filled with dreams, the content being usually violent and disturbing. Prophetic dreams have been experienced. The general affective state is becoming more like that which immediately precedes the attacks. Amnesia is partial as referred to attacks. A certain amount of the desultory type shows in her daily life. Examination showed irregular and fluctuating areas of anesthesia over the left side, a coarse, inconstant tremor of the left hand and arm, moderate visual limitation, considerable emotional instability, suggestibility; there are no memory gaps apparent; retention is good and grasp normal.

Psychoanalysis first showed an assault, incomplete, occurring six months before the first attack. This attack had been but partly reacted to; that is, although she had not forgotten it as a whole, yet certain elements in it had been lost and the exclusion process had taken care of the balance. The elements lost were those most sexual in tone, made up by the pressure of the assailant's body against her left side. These factors, thus brought up, seemed to explain the attacks. Each had the left-sided rigidity as a conversion symptom due to the excluded sex sensations. The first attack had occurred immediately after striking her bare body against a bureau in a dark room. Other varied impressions with an associative bond to the shock had seemed to initiate later attacks, an alcoholic breath, a street car where crowded against men, dreams with assault content or hallucinations of a man's face. The attacks, the dreams, the content of distractive states, the hallucinations were all brought out and supposedly expanded. Yet no change followed in the attacks; there was only a better affective state. This meant, of course, incomplete work. About this time she began to complain of violent nausea, sudden in onset and termination, accompanied by a mental state of aversion and disgust. She gave here that which is common to such cases, a misleading cue, directing its origin to an unintentional exposure by her husband of his person. It was soon brought out that one month before this, a workman on the road where she was walking had acted as an exhibitionist before her. Yet the effect of this upon her seemed not new; it had merely served to crystallize feelings previously known to her, but rigidly excluded. She had always had an aversion for men; as a young woman she had gone with but few; back of a liking for those who were personally agreeable to her, there lurked a latent aversion. She had married only after many delays and against an apparently unconquerable dread of the state. As these statements came out the reactions became more marked until, finally, there came to light the experience which really formed the beginning. When a child 7 years old she had been met in the woods by a man, a degenerate, who forced her to touch him, thus polluting her left hand. She cleansed this hand upon her frock. She had said nothing of it. The memory had been partly lost, due in a way to the age when it occurred and to the exclusion directed toward it upon its reappearance. As an actual memory it had functioned little, but as a dissociated fragment it had been tremendously potent. Its action was progressive and permeating to a degree that can be no more than sketched. It produced first the aversion toward men and boys in her childhood. After puberty, when her work threw her among girls whose talk was not clean, it began to lend its deterrent effect to topics which, otherwise, might have been entertained with the indeterminate desire of that age. As she grew older and with this there appeared the normal sex tone, this underwent unusual exclusion due to its borrowed, unpleasant value. Both because of its constant exclusion and its physiological strength the sex complex became hyperesthetic; yet immediately upon its return, due to its driving power of repressed and unfulfilled desire, there came the aversion, disgust and fear, producing that indefinite affective state which had preceded the assault preceding the first attack. This assault had with it a direct physical element which associated itself immediately and effectively with the dissociated or excluded stuff of her early years. Yet at this assault the dissociation had been slight and only those sensory elements were lost which most clearly were bound to the childhood experience. The exclusions, however, had been difficult in greater degree from this point on, due to the increase in strength. Added to this, the first attack occurred under conditions where the normal libido was increased to a point impossible for the exclusion to work effectively. The chance sensory element of the bureau touching her bare side brought in all the associative bonds described in her history; the intrusion of this sensory complex above the threshhold of consciousness obliterated the stream for a moment with the production of a state, which, in its essentials, was sexual. All the attacks were thus conversion processes of sex states. Later analysis amply proved this. The percolation of the same

elements into her dream states with their sex symbolization, the hallucinations, the confusions, the amnesias, the varied sensory disturbances were demonstrated but cannot here be entered upon. The rapid and satisfactory termination afforded a clinical proof of the reality of the cause and the efficiency of the measures.

This case, terminating the series, serves in an incomplete way to stand for an example of Freud's method in hysteria quite as the initial case exemplified Janet's. It has in it the early sex factor, the exclusion process, the displacement, the unfulfilled desire, all traceable through the conversions, substitutions, symbolizations in the line of symptoms. Of the first it embodies a clear example. Freud has been insistent in his emphasis upon the frequency of sex incident in early life among neurotics. There is found further substantiation for his theory that no dissociation in the sense of Janet's occurs here, but that the process is the normal memory loss common to early impressions, those especially persistent being limited to the indeterminate sex life. It is not in place here to discuss the biological insufficiencies of this theory, but among neuroses it finds much support. The exclusion process is seen to have markedly increased at about the time when the normal libido appeared. Its effect is easy to follow and permits of a clear distinction from the direct dissociation, for even in the assault, nothing of Janet's type could be demonstrated. The functioning of the unfulfilled desire is marked plainly in the successive intrusion of content above the threshhold under the varied forms of conversion into somatic symptoms, sensory symbols, etc., showing no organization as in the first case where the mass of dissociated stuff was continuous and integrated, but appearing more as a series of associations, suffering varied mutations with successive exclusions and determined solely by a content of sex and a conation of the unfulfilled desire.

These four cases may be made to stand for three general groups in hysteria when viewed from the standpoint of mechanism and applied therapy. The first class, marked by Case I, is a limited division. This particular case might well be called a shock neurosis or neuropsychosis. It is usually contended, however, that such cases have a substratum of hysteria and, for this not entirely cogent reason, here they are thrown. They are distinguished by the intensive, massive, psychic shock, the clean-cut dissociation, the organization of dissociated content and the effect upon consciousness by the double process of absorption and intrusion. The therapeutic method, applicable here is hypnosis in light degree, for this is quite sufficient to allow the hyperesthetic content to rise. There may at first be a false show of irrelevant stuff, but a tolerable persistency soon touches on the complex. The manner of appearance is characteristic: It rises as a living, present experience with a reaction that leaves no doubt of its veridity. The connection is readily pursued because of the organization, synthesis being speedily effected. As 75 per cent. of hysterics are hypnotizable and the required degree here is light, this necessity is not onerous. It is quite another story with other classes of neuroses and in itself constitutes a formidable argument there against the application of this particular method.

The second class, illustrated by case IV, has a far wider territory. It is characterized by the sexual basis of its psychogenic factors, depending more upon the content of the shock and less upon the sensory momentum, by the volitional exclusion process with its gradual dislodgment instead of the cleavage dissociation, by the deterministic direction given to these dislodged associations issuing from the unfulfilled desire but without real organization and by the effect upon consciousness produced by the conversion of these elements into intruding somatic symptoms in place of any pure absorbing and displacing tendencies. It is hard to give a clear description of the method without overloading the detail. Hypnosis is not used. The patient is quietly swung into an amplification of his history. Specific points he is encouraged to enlarge without let or hindrance; that is, at these points he is urged to bring into words everything that passes through the mind, censoring or suppressing nothing. This is difficult at first, for the habit of exclusion is so strong as to require constant overriding. The seizure of the excluded points is especially useful, for from here the lines open up. The view backward into early years is always maintained while the generalizations of sex content and the unfulfilled desire aid in making the method less blind. The purpose throughout the proceeding is to bring about conditions, issuing from the demonstrated continuity of associations, that may lead to a complete reaction by the individual to these points thus illustrated. Necessarily this means not only displaying before the patient the mechanism but aiding him in handling the content in a healthy manner, in interpretating it for him, explaining its intricacies and its crudenesses. The work is time devouring even with long experience and possible here only of abridgement through acquired skill in picking up clues by an intelligence trained in the selection of those vital to the series. Despite this handicap, in handling intricate and involved cases it stands as the one method which produces results.

The third group is the largest and has, perhaps, slipped attention because it is a third alternative. It is characterized by the presence of both mechanisms in an incomplete form. Freud's is usually the fundamental with the other superimposed. It seems to be with many of this class that the constitution or mental make-up has in a way been able to compensate for the conditions issuing from the exclusion process and to maintain a working balance until the terminal shock is added as the last straw. When this can be cleared away by Janet's method the patient may find himself so relatively improved that it is considered a cure. This is, of course, fallacious as shown by case II in the presenting of residual minor symptoms. It is necessary to remember when the underlying state has not been changed that recurrences may appear. In other cases it seems better not to disturb the regained balance through too remote extensions of the free associative work of Freud, particularly where there exist complexes which had best remain submerged for the patient. A general direction toward more wholesome ideas may be quite sufficient to arrive at a practical result. Another working plan can be gained in this class of cases. The hypnosis will often let one in upon a point where the lines most necessary for the work of Freud converge. It saves a tremendous amount of time in orientating the investigator as to the raw part of the life story. Further it is possible in this light state to effect certain alterations, make affect substitutions, carry out other changes through suggestion where one has the manner of their production mapped out by previous analyses. These short cuts are facts to be considered in dispensary

work among hysterias. Without their aid the analyses of 60 per cent. of the hysterias in my clinic at Roosevelt Hospital would be frankly impossible, for one here has to get the practical results in the many rather than refined and extensive analyses in the few. This should in no way, however, prejudice the execution of a full sequence whenever possible. The point is mentioned solely for its usefulness in getting working results under conditions not ideal for the more extended methods.

The subject-matter of this paper has shown a strict limitation to hysteria. This has been done not only for the purpose of getting at a fair comparison of Janet's and Freud's work with the practical results issuing from this, but also that a certain clinical unity might be retained. It is inevitable that a new method should lead to its overemphasis with a corresponding reduction in the careful determination of the clinical complex and groupings of the cases studied. The result is twofold disastrous. It is certain to prejudice illy the immediate work, for the investigator thus proceeding is toiling in the dark, but, more important, the failures resulting from this are liable to be laid to the inefficiency of the method where they do not belong.

The rapidly widening range of these procedures into neurasthenias, anxiety-neurosis, imperative ideas, obsessions, manic-depressive group, precox and paranoia, make this warning necessary. The underlying mental make-up of these classes is so different, their constitutional resistiveness and lability is so varied, the interdependability upon physiological causes so manifold, that a disregard of these essentials produced by an infatuation with method can lead to nothing but ridicule and failure.

Conversely, where the method is pursued with a full knowledge of the particular psychological and clinical make-up of the case, the results are certain to be favorable either in a complete resolving of the case or in the attaining of a much greater definition of clinical lines than has been possible heretofore.

55 East Fifty-sixth Street.

EXTERNAL URETHROTOMY WITHOUT A GUIDE.*

By C. L. GIBSON, M.D.,

NEW YORK.

SURGEON ST. LUKE'S HOSPITAL, CONSULTING GENITOURINARY SURGEON TO THE CITY HOSPITAL.

The operative treatment of deep, tight strictures of the urethra which have been found impermeable to any instrument is generally based on opening the urethra anterior to the stricture on a staff introduced so far as feasible. Then comes the search for the posterior end of the urethra which, even in the hands of skilled operators, is often a prolonged and disheartening procedure and not infrequently has to be abandoned and resort made to the humiliating procedure of retrograde catheterization by a suprapubic incision. In the hands of the inexpert it is a most fearful procedure to witness. Consequently my belief is that such unsatisfactory methods should be abandoned, and for them I beg to submit the following technique. Attempts to pass filiform bougies should not be pushed to such an extent as to provoke urethral reflexes or entail a delay lasting sometimes for days. Prompt relief should be given by performing external urethrotomy without a guide, aided, perhaps, by some of the expedients to be hereafter described. The posterior urethra having been opened, a guide can in the great majority of cases be easily passed from the posterior aspect of the stricture and the division of the stenosis completed *secundem artem*.

The several steps are as follows: A general anesthetic can almost invariably be administered, for the procedure is so rapid that anesthesia has to be pushed up to the point of securing relaxation for only a few minutes. An exaggerated lithotomy position is of utmost importance.

For locating and opening of the posterior urethra, the classical Cock's operation has never failed me. It is performed as follows:

The index finger of the left hand is passed into the rectum, palmar surface upward, so far as it will go. It is thus in contact with the prostate, and is withdrawn slowly till it just leaves the prostate, where it is held as the guide to the membranous urethra. An inch and a half incision is made with one stroke of the knife through the skin, ending just at the margin of the anal skin. At the midpoint of this incision, the knife, held perpendicular to it, is entered and deliberately pushed through the perineal tissues just superficial to the rectum (keeping a bridge of tissue between the knife and the "guiding" finger) and proceeding steadily in the mid-line till one has the sensation of entering "something," which is the well-dilated membranous urethra. The knife is held steadfastly in place (and *not* withdrawn, as recommended by Watson and Cunningham in their description of this operation) by the right hand. The operator removes his finger from the rectum, takes off his rubber glove and now

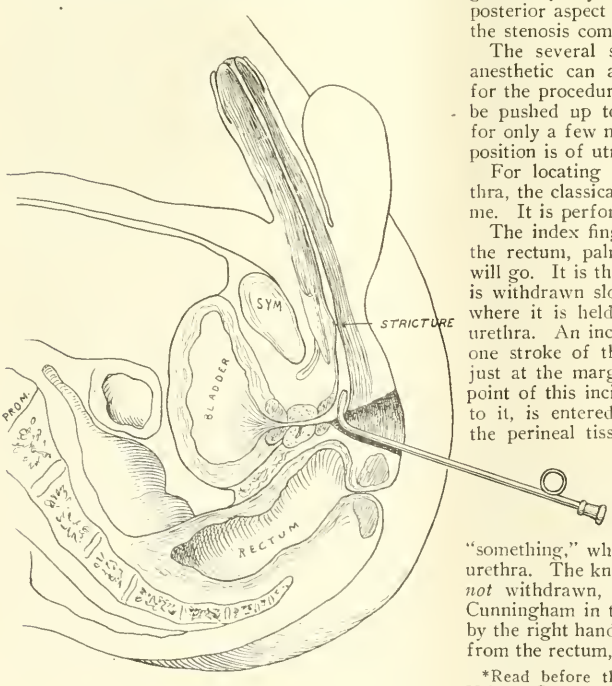

Fig. 1.

*Read before the American Association of Genito-Urinary Surgeons, May 5, 1910.

continues to hold the knife steadily in place by the left hand while he seeks to pass alongside the knife a suitable probe, director, or catheter into the urethra. A combination probed director catheter, which I have devised, serves my purpose best. This, or some other suitable form of catheter, having been pushed through the lumen of the urethra to the bladder until urine escapes, proves absolutely that the posterior urethra has been correctly opened; nothing short of this demonstration must be accepted. Not until the urine actually so escapes can the knife be deviated from its original position, but now it can be withdrawn provided that the catheter or guide still remains in position, for it is this failure always to keep something constantly in the urethral path that gives rise to so many vexatious accidents, for the guide once withdrawn it may be difficult or actually impossible to locate the urethral opening again. Having demonstrated the access to the bladder, our perineal and urethral incision, originally little more than a puncture, is enlarged with a blunt-pointed knife till it readily admits a finger, which thus approaches fairly closely to the posterior end of the structure.

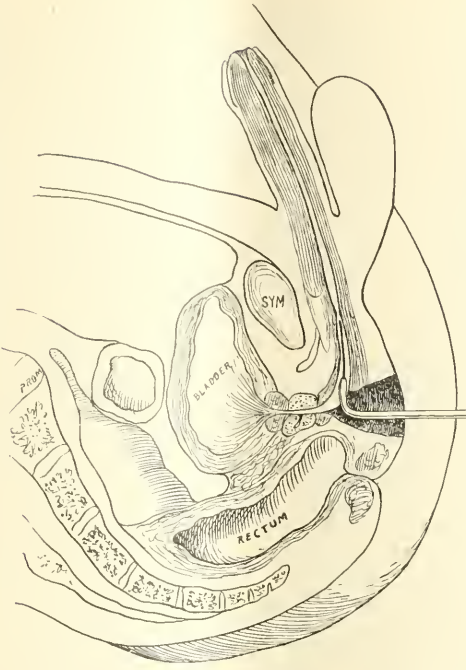

Fig. 2.

Step two consists in dividing the deep stricture, to which we have a ready access through the urethral wound, and experience shows that it is usually quite easy to penetrate such a stricture from behind forward. Therefore, I next seek to pass a small urethrotome, bougie, or other suitable instrument introduced into the urethrotomy wound and directed upward, towards, and through the anterior urethra. When this act is not readily accomplished I find I can almost invariably introduce a filiform by using my retrograde filiform carrier. (Fig. 1.) This instrument resembles a Bellocq cannula and has a minute lumen holding a filiform snugly; the beak is introduced into the urethrotomy opening, directed towards the stricture and by pushing the filiform forward a little gentle maneuvering usually causes it to slip easily through the stricture (Fig. 2) and come to present at the meatus and giving us control of the situation.

Fig. 3.

My own procedure is to thread the small calibered straight staff of the Flührer urethrotome over the filiform (Fig. 3) and push it deliberately through the stricture till the point of it lands on my finger introduced into the urethral opening below. The knife is now fitted into the staff and pushed home through the stricture. The cut made by this small instrument is sufficient to permit the passing of the Otis urethrotome, and the operation is completed by dividing the stricture to its full size, approximately 30 of the French scale. A sound of that size is introduced by the meatus and is made to demonstrate that it readily reaches the bladder and the operation

proper is ended.

Bladder drainage is instituted in all cases; how long it will be continued depends on the conditions — cystitis, gangrene of the tissues, bleeding, etc. Two or three days is my rule in simple cases. The tube used is a special heavy rubber perineal catheter, caliber 30-34 French scale with two generous openings, one at the end and one at the side. The demonstration of the efficiency of the drainage should be made before the patient leaves the operating table.

Normal salt solution is used for irrigating fluid. The catheter is temporarily connected with the irrigating apparatus and is introduced through the perineal wound, while the stream of fluid is running through it with some force; this procedure prevents the eye of the tube becoming clogged with clots. Eight ounces or so are introduced and then allowed to run out, and this washing is repeated until the fluid comes back quite clear and it is demonstrated that the bladder is free from clots. It is ascertained also just how little of the catheter it is necessary to have lie within the bladder and yet drain efficiently—too much will produce discomfort. Packing is applied around the catheter if necessary to check oozing The catheter is securely fastened in place by transfixing it and the skin edges with a safety pin. This procedure is most efficient in maintaining the catheter exactly where it should be and saves the patient and the surgeon discomfort and anxiety. Siphon drainage is subsequently maintained.

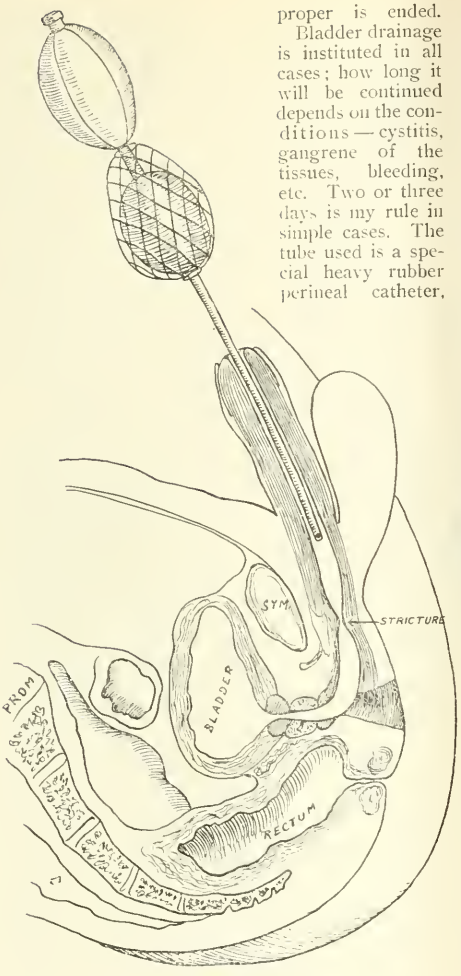

Fig. 4.

The above may be described as the normal operation, and very seldom requires more than a few minutes for its successful performance. The following modifications may be mentioned: For the casual operator Cock's operation, as just described, may have a good many terrors, and it may seem desirable to possess some further landmarks to the posterior urethra. Eight years* ago I called attention in this association to an infallible method, namely, making the posterior urethra taut by traction on the prostate. Briefly stated, the superficial perineal tissues are incised; a hook passed through the rectal wall transfixes the prostrate, and by traction on it the tightening of the posterior urethra is felt by a finger introduced into the perineal incision with the utmost distinctness. The method has the disadvantage even if theoretical, of possibly infecting the prostate and has probably properly received little indorsement.

I have, therefore, suggested another method which may be of some value. A metal catheter is introduced into the urethra down to the site of the stricture and to it is attached an air bulb. (Fig. 4.) An assistant keeps the penis firmly grasped to prevent the escape of the air

Annals of Surgery, Vol. XXXVIII, p. 518.

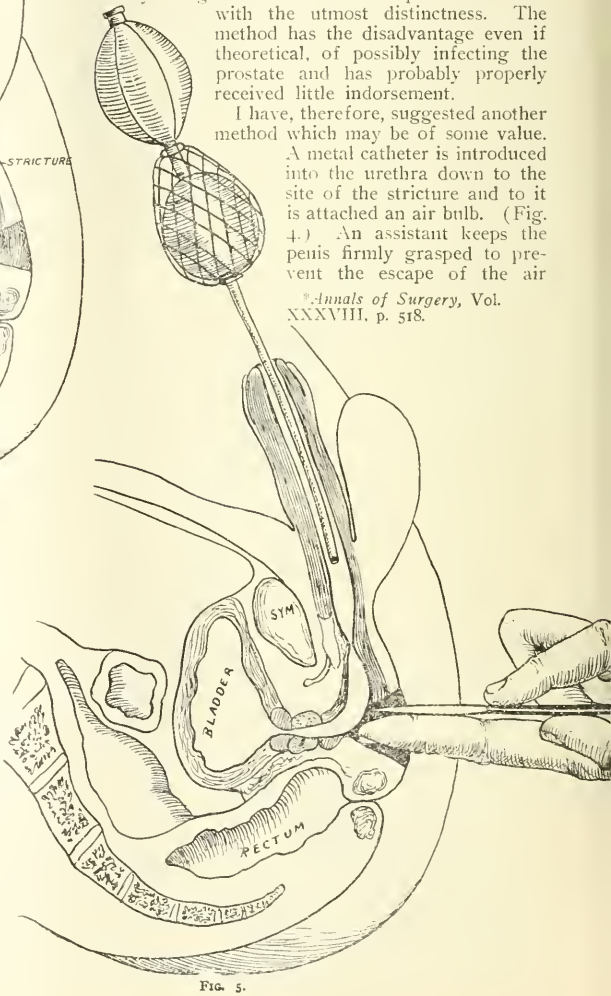

Fig. 5.

from the meatus. The perineum is incised superficially and the finger (Fig. 5) introduced into the wound. Air is now pumped in and one perceives its passage through the stricture and into the posterior urethra with a reasonable degree of accuracy.

To return to the question of introducing a guide through the stricture after the posterior urethra has been opened, I would like to call attention to the ease with which an instrument of suitable pattern may be passed through from the meatus with the aid of the finger introduced into the opening, so that we can gently steer or "worm" through such an instrument, the guiding finger protecting us from a false route. The small staff of the Flührer urethrotome has rendered me very good service in this connection.

Finally, it may be borne in mind that if the bladder has been properly drained one need not feel chagrined if for any reason—expediency, lack of suitable instruments, the bad condition of the patient—one does not succeed in passing through the stricture, for repeated experiences have shown that the stricture tends to relax appreciably after the urethra has been sidetracked and put at rest by the bladder drainage, and that after two or three days one can easily pass an instrument sometimes of considerable size through the previously impermeable constriction.

VACCINES IN THE TREATMENT OF VARIOUS BACTERIAL INFECTIONS IN INFANTS AND YOUNG CHILDREN.*

(PRELIMINARY REPORT.)

By E. MATHER SILL, M.D.,

NEW YORK.

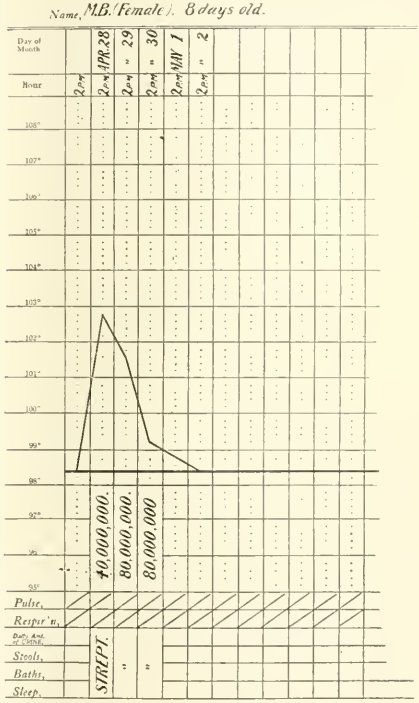
ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY IN DISEASES OF CHILDREN. LECTURER IN DISEASES OF CHILDREN AT THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

Sir Almroth Wright opened up a new field in medicine and gave to the world most valuable knowledge when he announced in 1903 that, in order to have phagocytosis take place it was necessary that certain constituents be present in the blood serum, which he assumed acted upon the bacteria in such a way that they may be destroyed by the leucocytes. These bodies he named opsonins. Wright and other investigators have also shown that the opsonins in the blood may become much reduced so that phagocytosis takes place with much less activity, and the body is in the same measure more susceptible to bacterial invasion. We understand then by the opsonic index the power of the blood serum upon bacteria to make them more easily destroyed by leucocytes as compared to the action of the normal serum. Nature's way of increasing the opsonins in the blood for an emergency in the struggle with diseases is as yet purely guesswork; it has been found, however, that this can be done artificially by the injection subcutaneously of dead bacteria in suspension in the shape of vaccines. It has been shown by the microscopic count of the germs in the phagocytes before and after injection of vaccines that phagocytosis is increased by their use, and this is the most powerful means of raising the opsonic index of the blood. Ross has shown there are three classes of indices:

1. Local infections in which the bacterial products have not entered the general circulation, and on that account there is no reactive stimulation of the general system.

2. Cases in which the bacterial invasion of the general system is so great that the opsonogenic powers of the system are overwhelmed.

3. Cases of such low vitality that they are not able to react to the stimulating influence of the toxins. It is obviously only in the first group of cases that the treatment by bacterial injections may be expected to give good results. This group of cases include furunculosis, acne, carbuncles, boils, and walled abscesses, and early cases of pulmonary tuberculosis, chronic and acute suppurative otitis media, old unhealed abscess cavities, and erysipelas, and gonorrhea. These opsonins are specific, in other words, for each of the different varieties of



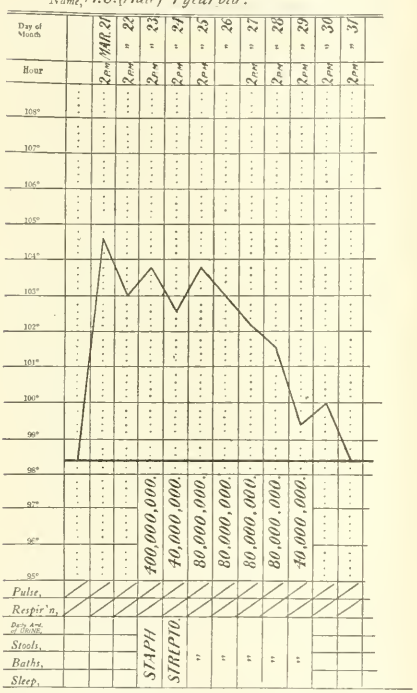
bacteria phagocytosis must occur, so that the opsonic index may be very high for one variety of bacteria and low for another, thus, in order to get beneficial results from the treatment of these various infections it is evident that a vaccine must be used made from the same kind of dead bacteria as is found in each infection.

Through the courtesy and interest of Parke, Davis & Co. I have been abundantly supplied with a variety of vaccines and have thus been able to treat a variety of infections with a view not only to determine the usefulness of vaccines in these infections in children, but also whether their use was accompanied by any danger or untoward results, as well as to satisfy myself whether or no the stock vaccines could be used with as great advantage as the autogenous vaccines.

*Read before the City Hospital Alumni Society, April 13, 1910.

My experience extends over a period of six months, in which time I have treated 49 cases by means of vaccines. Of all these cases I have kept careful notes and no case was pronounced cured until all signs of any pus or a discharge had entirely disappeared for some time, with no recurrence. Of these 49 cases 39 were subacute or chronic otitis madia, the ears having discharged from a few days to two years, local treatment having had only slight effect. There was one case of erysipelas in a child one year of age, and one in an infant eight days old, two cases of multiple abscesses of the scalp, two cases of suppurating glands of the neck, two cases of pneumonia in babies, one case of gonorrheal ophthalmia in a baby of three weeks, one case of acne of eight years standing.

Of the 39 otitis media cases 28 were cured, 10



improved while under treatment, and 1 did not improve. Both cases of suppurating glands of the neck and both cases of multiple abscesses of the scalp were cured. In one case of pneumonia the vaccine apparently brought about a rapid cure as the crisis came on the third day of the disease, and in the other case there was marked improvement of the symptoms. The erysipelas cases were cured. The case of acne was cured after a period of six months, having received an injection of 800,000,000 staphylococcus aureus each week. Thirty injections were given this case in all.

The case of ophthalmia improved rapidly under 5 per cent. argyrol and gonococcus vaccine and was apparently cured when last seen.

The earlier the vaccines were used after the discharge from the ears began the quicker was the cure, one or two injections being sufficient in most cases. Young babies seemed to require fewer injections to bring about a cure than older children, especially if the ears had been discharging only a short time, but this was not always the case; some children who had had a purulent discharge for two or three weeks were cured with two injections, and one case of five months standing received two injections, at intervals of five days, which brought about a cure. Other cases that were subacute, of a few days' duration, required numerous injections; thus a boy ten years of age, both of whose ears had been discharging for three days, showed by culture growth a mixed staphylococcus infection. In this case eleven injections of 400,000,000 each of the combined staphylococcus aureus, albus and citreus vaccine were given over a period of one month and brought about a complete cure. This boy was run down and ill nourished, which, no doubt, had something to do with the length of time necessary to bring about the cure.

Another case was that of a child three years of age, who had had a purulent discharge from the ear for over a year that had resisted local treatment. In this case nine injections were given over a period of twenty-eight days before all discharge had stopped, and the child was pronounced cured.

Another interesting case was that of a child a year and a half old, whose ear had been discharging for two weeks; this child was suffering from a severe attack of whooping cough. Culture growth from the discharging ear showed diphtheria bacilli and the staphylococcus albus to be present. Five thousand units of antitoxine were given, and 400,000,000 staphylococci at 6 different times were required to bring about a cure. The majority of cases required only two or three injections, and lasted from a few days to two weeks after vaccine treatment was begun.

The method of procedure in each case was to take a culture from the ear by means of a fine cotton applicator. This culture was allowed to grow for twenty-four hours on blood serum in the ordinary culture tube, placed in a thermostat. At the end of twenty-four hours the growth was stained with Loeffler's blue and examined under the microscope, and the vaccine corresponding to the germ found was injected subcutaneously. A variety of bacteria were found, staphylococcus aureus, albus, and citreus combined, or any two combined, or each separate; also streptococci. These bacteria were also found with the influenza bacillus, the hay bacillus, diphtheria bacillus and others, also the pneumococcus and other cocci.

The majority of cases showed one or more varieties of staphylococci, either alone or with streptococci. The vaccines were given in doses of from 200,000,000 to 800,000,000 staphylococci, from every two or three days to once a week; streptococci were given in doses from 40,000,000 to 80,000,000 bacteria, in some cases as often as every day, but in most cases at the same intervals as the staphylococci. Pneumococci were given in doses of 40,000,000 every day or two; gonococci were given in doses of from 20,000,000 to 100,000,000 once a week or oftener. The children treated were from a few months to ten years of age, the majority, however, were under five years and most of these under three years. The vaccines were given with the ordinary glass hypodermic syringe, previously sterilized by boiling, under antiseptic methods, and the injection

was made either in the buttocks or abdominal muscles. The opsonic index was not taken in these cases, and it does not seem to me to be necessary, and for the ordinary practitioner it is entirely too complicated a proceeding. The clinical symptoms of each case were relied upon to determine the amount of vaccine given and the frequency of the injections. The only treatment in the otitis media cases other than the vaccines was washing the ears out with boracic acid solution.

In a severe case of erysipelas in a baby one year of age, I believe the injection of large doses of streptococcus vaccine was the means of saving the child's life. When first seen, February 21, the erysipelas involved the whole of one leg up to one inch of the knee; the temperature was 104.6° F., and the baby appeared to be pretty sick with more or less prostration and rapid pulse. A fever mixture and cold sponging were given and ichthyol ointment applied. On the 22d the temperature was 103° F. and the erysipelas had extended one and a half inches above the knee. On the 23d the temperature was 103.8° F., and the erysipelas had spread half way up the thigh, 400,000,000 staphylococci combined were given with a continuance of the other treatment. On the 24th temperature was 102.6° F.; the inflammation had spread all over the legs and two-thirds of the way up the thigh, in fact nearly to the groin; 40,000,000 streptococci were given and aluminum acetate solution applied to the leg in the shape of a wet dressing. On the 25th the temperature was 105.8° F., and the erysipelas had spread to the trunk, all the left buttock being involved; 80,000,000 streptococci were given. On the 27th the erysipelas had extended one and a half inches, but looked paler, and was fading on the leg; the temperature was 102.2° F., and the child seemed much better; 80,000,000 streptococci were given. On the 28th the temperature was 101.6° F., and the erysipelas had advanced less than an inch, and the redness on the leg and thigh had practically disappeared; 80,000,000 streptococci were given. On March 1 the temperature was 99.5° F., and the erysipelas had receded about an inch and only a small area remained. The child looked pale. Forty million streptococci were given and a bichloride dressing applied. On March 2 the temperature was 100° F., and the inflammation had practically disappeared. On March 3 the temperature was normal and the erysipelas had entirely disappeared and the child seemed perfectly well.

Dr. Kerley states in his book that erysipelas is a particularly fatal disease in infants, 95 per cent. of the cases being fatal in the new-born and 50 per cent. of his cases occurring under one year being fatal.

The other case of erysipelas was in a small female infant eight days old. It was a streptococcus infection of the umbilical cord. The erysipelas began or was noticed first by the mother about 12 o'clock, and at 2 o'clock I saw the child, who then had a temperature of 102.8° F. The erysipelas involved both vulvæ and extended nearly to the umbilicus. At this time 40,000,000 streptococci were given, and a wet, 1 to 5000 bichloride of mercury, dressing applied. On the following day, the 29th of March, the temperature was 101.5° F., and the erysipelas had extended half way down both thighs and over the lower part of the back and buttocks. Eighty million streptococci were injected, and a wet dressing applied as before. On the 30th of March the temperature had dropped to 99.2° F., and although the inflammation had extended slightly toward the knee it looked much paler over the whole area and the child seemed much brighter and better, and there was hardly any discharge of pus from the umbilicus. Eighty million streptococci were given and dressing applied. This case made a rapid and uneventful recovery after this and no more injections were necessary, although I fully realize that more cases of this serious infection should be studied and treated with the vaccine before we can say we have a specific for the disease, yet the signal success I have so far had with the use of the vaccine, and its apparent superiority over all other previous modes of treatment, make me feel even now quite confident that further trials will prove to be equally convincing.

Of course, the whole idea of the vaccine treatment is to raise the opsonic index of the blood so that the system may overcome the infecting organism whatever it may be.

The effect locally of a vaccine injection is to cause slight redness and tenderness, which last a day perhaps, and in some few cases two days. There is slight fever in some few cases of 99° F. to 101° F., which lasts for one and in exceptional cases two days, but no other systemic effect has been noticed except that the child may have malaise for a day following the injection. One case that resisted treatment most stubbornly, being least responsive to the vaccine, was a case of acne. This case was eventually cured after thirty injections, one given weekly.

My experience leads me to believe we have a valuable and powerful aid to the treatment of various local infections in the use of vaccines, and that our armamentarium in these cases will be materially increased by their use, since of the hundreds of injections I have given no untoward condition has resulted.

142 West Seventy-eighth Street.

A THEORY AS TO THE ORIGIN OF LEPROSY.

By JOHN ATCHERLEY, M.R.C.S. (Eng.) L.R.C.P. (Lond.).

San Francisco, Cal.

Twenty years' residence in the Territory of Hawaii has enabled me to make use of the unique opportunities that the Islands afford for collecting facts and making observations concerning leprosy. In addition to the knowledge thus gained, I have profited by the last three years, which were devoted exclusively to the treatment of cases and investigations into the origin of the disease. Part of the results of this work are embodied in the present theory as to the origin of leprosy, and the means by which it is contracted, which I now offer for consideration.

Briefly stated then, the theory assumes the following: Leprosy is a chronic diathetic disease of gradual onset and irregular course, characterized by an inflammatory fibroid degeneration of the nerve tissue generally, which precedes the deposit of the lepra bacillus, and any other manifestation of the disease. The nerve degeneration is the direct consequence of defective pabulum supplied to it by the blood, which again is the result of improper food ingested by the individual. The theory is based on the fact that the pathological changes in leprosy bear a very remarkable and striking analogy to the corresponding changes in scurvy; and the position of the lepra bacillus is explained by that of the

micrococcus, which in scurvy is found in chains along the track of the degenerated arterioles. This explains the suggestion of the term "scurvy theory."

The incubation period supposed to exist in leprosy seems to be a myth. Where a disease is chronic from the outset, and with no initial symptoms, and there is no means of finding the date at which the disease was contracted, it appears absurd to speak of an incubation period. Considering the extreme length of the period—one to seven or more years—that it is said to run, the idea seems to have had its origin in an unconscious desire to provide an argument to account for facts which, in certain cases, would otherwise be strong evidence against the disease being acquired by contagion; such cases are obviously of the kind where a person develops leprosy, although he has not been in contact with a leper for say, seven or ten years.

Leprosy has its varied points of onset within certain limits, but these are determined by the position of superficial nerves. The time however of contracting the disease cannot be known by inoculation, for no one ever really succeeded in inoculating leprosy; and if this theory is the real explanation of the disease, no one ever can. One might just as well try to inoculate scurvy.

Evidence on which the Contagion Theory rests.—However strong the clinical evidence may be against the spread of leprosy by contagion, there is always the presence of the lepra bacillus and the hope of success in making cultures, or in inoculating an animal, to sustain the belief of a large majority in contagion. The conviction is with many of us hereditary, and dates from the times when numerous other diseases undoubtedly contagious were included under the term leprosy, and supposed to be leprosy, thus the signs of tuberculous disease of bones and skin, the manifestations of secondary syphilis, the various forms of ringworm, and malignant pustule—these are all contagious diseases which resemble leprosy enough to be mistaken for it.

Then there is the supposed strong analogy that leprosy is said to bear to tuberculosis which is always accepted without question, but on examination it consists merely in the shape and similar staining qualities of the respective bacilli, and the fact that tubercles are formed in both diseases, but these tubercles are widely different in structure and growth. The tubercles of leprosy are vascular and reach a large size, while those of tuberculosis are without vessels and break down early into pus. Tubercle bacilli will grow in any tissue and even outside the body, but leprosy bacilli will grow only in degenerated nerve tissue.

Very few are aware that the analogy which leprosy bears to scurvy, as already pointed out, is far more marked than any it can be shown to bear to tuberculosis, and that in addition to this, leprosy also shows a strong analogy to a group of diseases, which like scurvy, are admitted to have their origin in improper food ingested by the individual; this group includes: leprosy, scurvy, pellagra, podagra, and urticaria.

Facts and Arguments Bearing on the Main Question of the Origin.—(1) Although lepers are continually landing at such crowded seaports as Marseilles, London, Liverpool, etc., no epidemic has ever been known to have even threatened an invasion of these places, a misfortune which would certainly have struck the ports in question, had leprosy been at all of the contagious nature that is generally attributed to it.

(2) Although numerous cases can be found where leprosy was contracted without close contact, or without contact at all, with another leper, there are none to be found of the opposite kind, where the disease was contracted through close contact, and by no other means.

(3) Infants never have leprosy. The earliest age at which a child manifests leprosy is about five years, when it has lived long enough on improper food for this agency to produce the disease.

(4) The infant of a leprous mother is always free from signs of leprosy, even when the parent has severe lesions. The infant of a leprous mother may or may not develop the disease at the age of five years, but in case it develops leprosy, the disease is the result of improper feeding, and cannot be looked upon as evidence of contagion and the existence of a hypothetical incubation period.

(5) Segregation must needs fail to accomplish what is intended; it can only separate a certain proportion, because so many cases cannot be recognized in the early stages of the disease, many have the initial symptom within the nasal cavity, and in many other cases the first indication is in the foot, and in both these conditions the disease may be hidden for years. Segregation teaches the community, in which it is enforced that leprosy is contracted only by contact with another leper, and that they need not therefore look to their food as a possible source of danger in this respect. In this manner segregation may be said to fasten the disease on the locality where it is enforced.

(6) Habits are certainly contagious, which explains the case where a man living with a leper will sometimes, if the association be long enough, contract the disease by learning to take and eat the same kind of food.

(7) The cases of spontaneous cure that occur occasionally, and the way in which the disease will in the same case sometimes advance, and at another time stand still, are to be explained by corresponding variations in the quality of the diet, and these variations in diet are often the result of changes of residence. Thus a man afflicted with the disease while getting worse employed as a fisherman, will improve if he transfers to an inland cattle ranch, involving the necessary alterations in the nature of his diet.

(8) Hereditary influences have left in most of us an innate conviction that leprosy is contagious, brt this dates from the remote period when many other diseases of an undoubtedly contagious character were confounded with leprosy. These include such diseases as tuberculosis of joints, and tuberculous skin manifestations, the lesions of secondary syphilis, various forms of ringworm, malignant pustule, and others.

(9) During a famine in one of the Islands of the Philippine group the inhabitants had nothing to eat save clams from the river, and a number of them developed leprosy. When the famine ceased and plenty was restored no further cases appeared, in spite of the fact that some of the same lepers are still living on the Island.

Statement of the Scurvy Theory.—Leprosy is a chronic diathetic disease, of gradual onset and irregular course, characterised by an inflammatory fibroid degeneration of the nerve tissue generally. This pathological change precedes the deposit of the bacillus lapra and all other manifestations.

The bacillus is found deposited in the track of the peripheral nerve trunks and the parts to which these nerves are distributed. Since it is present

as a consequence of the nerve degeneration, the bacillus is a result and not a cause of the disease.

The degeneration of the nerve tissue is a direct consequence of the defective pabulum supplied to it by the blood, which again is the result of improper food ingested by the individual.

The position of the bacillus is further established by the analogy that leprosy bears to scurvy, and to the other diseases included in the scurvy group above mentioned.

The origin of scurvy in restricted diet, which is lacking in certain indispensable elements, has never been questioned, and once the analogy to leprosy is acknowledged, the bacillus must bear the same relation to leprosy that the micrococcus of scurvy (which is found along the track of the degenerated arterioles) bears to that disease.

The improper food, which is the chief or only factor in the production of leprosy, may be rendered unfit in two ways: (1) By the presence in the food of an excess of poisonous material, chiefly virulent microorganisms and their products. (2) By a restriction to certain kinds of food which are lacking in some indispensable elements or element. The effect of such food is to produce pathological changes in the nerve tissue of the body, analogous to those produced in the walls of the arterioles in scurvy, by equally improper food. The defect in the food is of course different in the two diseases, and it is this difference which alone prevents the two diseases from being identical.

It has seemed to the writer that no better proof of the real nature of leprosy can be offered, than that which is evidenced when leprosy is shown as a member of the scurvy group of diseases, and the analogies and interrelations of the members of the group are demonstrated at the same time. For this purpose it is only necessary to give the features, first of each member of the group, and secondly, to give the features they hold in common.

1. In scurvy, the improper food is rendered unfit by the absence of such indispensable elements as potash salts, citric and phosphoric acids. The chief signs are the skin lesions, ecchymoses, petechiæ, and scaly patches; then there are the bleeding into joints, swollen gums, and neuralgic pains in various nerve trunks, all resulting from a softening of the walls of the arterioles, which permits an oozing of sanguineous serum into the tissues with ultimate congestion and inflammation.

2. In pellagra, unfit food takes the form of bread made from mouldy maize taken for long periods. Signs in the skin are erythematous rashes over face, neck and arms, or parts exposed to the sun. These may be replaced by more scaly eruptions. There is often an extensive paralysis of mixed nerves leading to paralysis of muscles and consequently to deformities.

3. In podagra, the unfitness lies in the superabundance of nutritious food leading to a consequent retention of poisonous waste products, more being produced than the organs are able to excrete. This retention leads to atheromatous thickening in the walls of the arterioles and consequent impaired vasomotor action, which involves irregular blood supply to limited areas. Such parts are easily inflamed and a part exposed to injury, such as the ball of the great toe is peculiarly so. Hence the common sign is an acute inflamation of the metatarsophalangeal joint, including the skin covering it. At other times the skin is the seat of eczematous eruptions. The nerves are often inflamed giving rise to neuralgias and even to paralysis.

In examining the prominent features of this group of diseases, as expressed in their origin, manifestations and pathological changes, the following points are to be observed: (1) In every case the disease has its origin in the nature of the food ingested, and in food only. (2) In every case skin lesions form a prominent symptom and are very similar in the different diseases. (3) In every case, either the arterial walls themselves, or the vasomotor nerves governing their caliber, are impaired as to their action. In scurvy, the walls have undergone a degenerative softening, and in podagra an atheromatous hardening, while in leprosy and pellagra, the vasomotor nerves are paralysed.

From such evidence as this the conclusion must be recognised that leprosy, by virtue of the way in which its degenerated nerve tissue makes it a member of this group, is a disease as to whose origin in the nature of the food ingested, there can be no question.

Initial Lesions in Leprosy.—The point at which the first sign of leprosy appears is a variable one, and yet the same points repeatedly figure as the seat of an early lesion. It may be the mucous lining of the nose, or it may be that regular grouping of tubercles on the forehead, which gives the well-known "leonine aspect" to the features. There is a good reason for the same point being repeatedly attacked: where all the peripheral nerve trunks are degenerated, those will degenerate first, which from their position, are most exposed to injury. For this reason the nasal lining where the fifth and olfactory nerves are exposed to injury is more often the seat of the earliest or initial lesion of leprosy than any other; the symptom it produces is the chronic offensive discharge which may be present for years before its real nature is recognized. Next, the prominent parts of the face or the points of the terminal branches of the seventh and fifth nerves become spots on which maculæ begin to grow.

In the same way the hand is frequently the seat of the initial symptom, various paralyses and trophic changes occur in the fingers and other points of the hand, resulting from a lesion of the ulnar nerve, where it is exposed to injury at the bend of the elbow and frequently figure as the earliest sign of the disease.

Last, the internal plantar nerve, so frequently injured because of its position on the sole of the foot, which gives rise to another well-known lesion; this is the deep ulcer found between the first and second toes, or actually perforating the great toe at the tarsophalangeal joint. This is one of the lesions that lepers will cover with a boot and conceal successfully for years.

Food in Leprosy.—There is a special environment more likely than any other to favor the development of leprosy, where the character of the land is such that it can influence the food question. The land to fulfil these conditions must be a barren stony waste, devoid of vegetation, isolated enough to make communication with any place whence food can be procured rather difficult, where the supply of farinaceous food must be brought from a distance, and where firewood is almost entirely wanting. The sea-beach provides these conditions better than any other locality.

In these barren places the inhabitants must depend either on birds and animals they can kill, or

entirely on sea products, such as fish, bivalves, crustaceans, seaweed, and the one farinaceous food, which in Polynesia is taro-root or arrowroot, and in Asia, rice. Firewood being scarce, the rice or taro once boiled is kept too long in a moist state and is apt to grow mouldy.

It is now generally admitted that a long continued diet of mouldy maize is the cause of pellagra, but whether mouldy rice or taro has any share in the production of leprosy is a point yet to be determined. Animal food is scarce and seldom properly cooked before it is devoured, but whether cooked or uncooked, all parts are eaten, even the entrails.

As regards sea products, bivalves are eaten raw as a matter of course, and parts usually rejected such as the "beards," are included, and it is worth remarking that, according to authorities, the microorganisms found in shell-fish are more virulent than any found elsewhere. So long as they have rice or taro paste they will eat the smaller crustaceæ raw, including all parts.

Where leprosy is contracted by those who live among the civilized the choice of food becomes a matter of taste. There is an acquired morbid taste for a peculiar flavor associated with the food chosen, and this taste is invariably acquired by those who contract leprosy. It is difficult to describe, but resembles that produced by a mixture of freshly caught red-blooded fish, seaweed, and salt water. It is not attractive, but one can understand how a morbid liking for food having that particular flavor can be acquired. Those who have acquired the taste will prefer to eat fish uncooked, and even eat parts of the entrails as a delicacy

If the crustaceans are boiled at all they will eat parts other than the white muscles without discrimination. The same may be said as to bivalves, and in the case of ordinary fish the bones of the head are the favorite part. Lepers have told the writer how they could indulge in long drinking orgies, and during these periods would be entirely indifferent as to what they swallowed to help down the mouldy "poi" or taro-root that served them as food. At other times, or in other cases, they might have to experience long periods of privation, where the only addition to the indispensable taro would be some form of salt or sun-dried fish or plain seasalt and red chilipeppers.

There is no doubt as to the means by which the bacillus enters the body, which is through the alimentary canal. It is also found only in the deep layers of the skin, which indicates that it was not rubbed in from the outside. Much more investigation is needed to follow it through the liver and lymphatic system to the inflammatory areas where it is deposited. At present it can only be said that, in all cases of leprosy, there is a decided reduction in the relative number of the white elements of the blood, which suggests an explanation of how the bacilli are conveyed to their destination. Bacilli have been found by various observers in the liver, in the spleen, and in the blood.

If the scurvy theory is correct, it explains these facts in the same remarkable way it explains all that was otherwise puzzling and contradictory.

The scurvy theory explains cases of spontaneous cure in leprosy, and why at one time the disease will in the same case advance and at another time stand still.

It explains why the same remedy will succeed in the hands of one surgeon and not in that of another.

It explains, even on a food theory, how cases may be found at great distance from the sea.

It also explains why a leper improves when removed from the locality where he contracted the disease.

With those who adopted the food theory the difficulty lay chiefly in explaining the presence of the bacillus, but the present theory fully accounts for the bacillus and indicates its relation to the disease.

To collect material for this paper has been no easy task. I wish therefore to express my gratitude to Mrs. Atcherley for her aid in acting as interpreter to the leper patients, and in eliciting information and inspiring confidence.

1178 Eddy Street.

GENESIS OF HYSTERICAL STATES IN CHILDHOOD, AND THEIR RELATION TO FEARS AND OBSESSIONS.*

By TOM A WILLIAMS, M.B., C.M. (Edin.),

WASHINGTON, D. C.

MEMB. CORRESP. SOC. DE NEUROL. DE PARIS, MEMB. CORRES. SOC. DE PSYCHOL. DE PARIS, NEUROLOGIST TO EPIPHANY FREE DISPENSARY.

In the past, the term hysteria has been with reprehensible looseness applied to almost any excitable nervous state or show of emotion. The depressed and inactive states have been called neurasthenia; while the term nervous break-down is still more vague. We have nothing to do with such imprecise classifications; so let it be clear from the beginning that by hysteria we shall only mean "those symptoms susceptible of production by suggestion and of removal by suggestion—persuasion."[1] That is to say that hysteria is purely a product of an idea. Its mechanism is a psychological one; and it is to mental agents that we must look in order to influence it.

You may justly ask then in what neurasthenia[2] differs from this; and still more cogently the question may be put of psychasthenia. The former, when real, has nothing to do with suggestion; and is not even an affair of the psyche: it is a mere exhaustion of the nervous system due to bodily conditions, generally toxic or reflex; and its cure is a question of physiopathology and is a strictly medical problem.

Psychasthenia is the term given by the medical psychologist Janet to a mental state which is characterized by (1) a feeling of inadequacy without, however, the real incapacity of the truly fatigued; (2) a tendency to unreasoning fear or horror of anything or everything; (3) a sentiment of strangeness or unreality of self or surroundings.[3]

Phobias and Obsessions.—These morbid feelings lead to intellectual ruminations, doubts, and besetments, often of so irrational a nature that they cause moral distress. Hence, a vicious circle, an unpleasant "feeling-tate" causing distressing ideas, which in turn aggravate the unpleasantness of the feelings. For example, it is from a general feeling of anxiety that is derived the notion that one may have placed in the wrong envelopes two letters, or that one may have added wrongly a column of important figures, or that an injustice to some one has been done by us. Although the patient is reasonably sure that the incident has not happened, yet he cannot dismiss the notion, which besets him and works him up to a state of distress sometimes so violent as to be mistaken for an attack of hysteria or even insanity. When the

*Presented by invitation before the first congress of the American National Society for the Study of Exceptional Children, New York, April 21, 1910.

intellectual element predominates, we call this state an obsession; when the emotional factor is most evident it is called a phobia—that is, a morbid fear.

Now, these obsessions and phobias do not arise from suggestion; they arise, it is believed, from a physiological error in the working of the mechanism which determines the emotions. Of its exact nature we are at present ignorant, though many believe that the internal secretions play an important role; for we find strictly comparable states resulting from known perturbations of the thyroid and of the adrenal glands, the most important fabricants of internal secretions. Moreover, the remarkable exacerbations of psychasthenic symptoms at puberty, during menstruation, and at the menapause lead us to believe that the generative glands participate in the regulation of psychic functions, very likely by means of internal secretions.

A great many of these patients are labelled hystericals; and indeed it sometimes requires an expert to diagnose whether or not a patient's obsession or fear has arisen from a morbid idea or notion, or whether it is not merely the expression of a general emotionalism, and hence quite unamenable to psychotherapeusis of suggestion or persuasion.[4] By this I do not mean that mental therapy is useless; for it is of the greatest service in teaching the patient to bear his state without the natural undue alarm to which his feelings conduce until their significance is realized. For instance, it is very common for such patients to believe that their feelings are unique, that they presage some terrible physical malady, or that they are the harbingers of insanity. The idea of this does not mitigate their sufferings, but when you enable them to realize their true status, they are generally able to bear their ills. The practical difficulty is that they have usually met so much unconsidered optimism stalking in authoritative guise that they find it difficult at first not to believe that they are being soothed by medical mendacity, so often has this been imposed for what is imagined their welfare in persuance of the short-sighted policy of an immediate anodyne at all costs.[5]

Very different is the psychological mechanism of the hysterical obsession. It is typified by the following cases: After an attack of influenza, a woman returning in a crowded car from a shopping expedition, began to feel much oppressed and in want of air. The heart, enfeebled by the influenza poison, and we know not what others taken as medicaments and aliments, ceased to respond to the call upon it for a more rapid flow of blood so that aeration could be sufficient; and a faint ensued with the psychic accompaniments of irresistible terror and dread of dissolution. Never since has this woman been able to bring herself to go alone into a car; the very idea of doing so induces the fear of fainting. She is not obsessed by the idea so long as the question of entering a car does not arise; but although she knows her conduct to be unreasonable, she cannot bring herself to act reasonably about going alone in a car.

Another case[6] is that of a clergyman who once lost his voice from laryngitis while in the pulpit preaching to a large congregation. Although the laryngitis recovered, he continued to lose his voice whenever he attempted to preach from the pulpit before a congregation. He could rehearse his sermons from the same pulpit without difficulty when the church was empty. Nor had he any difficulty with his voice when there was someone on whom he could call to preach for him if he should fail. But on such occasions he never did fail. The ordinary incident of having to preach was the creator of the extraordinary dread of failure which he used to feel.

In both these cases it is a suggested idea which determines an emotion too powerful to permit of rational conduct. Experience shows physicians enlightened in psychopathology that the emotions cannot be mitigated until their causal idea is removed.[7]

The method of solicitude and sympathy merely reinforces the patient's belief in the validity of the idea for which sympathy is an implicit acquiescence. Still more injurious is direct medical treatment of the apparent physical disorder which results from the idea. For instance, a hysterical monoplegia, *i.e.* a paralysis of one limb induced by the patient's belief that it is disabled, should not be treated by the application of electricity or massage to that limb nor by the giving of an internal remedy which the patient is led to suppose is capable of removing such conditions. It is very bad practice, too, to pretend to perform an operation upon a patient who believes that she is inhabited by a lizard that she has swallowed.[8] Sometimes, it is true, a symptom disappears through the suggestion involved in such procedures; but it does so in a small proportion of cases only. It is a pure chance, and does not touch the cause; while by ascertaining and removing the root, we can generally cure permanently, as regards the present symptoms, at least.

An illustration of the method of treatment is afforded by one of my cases of traumatic neurosis;[9] for this condition is merely the expression of an induced fixed idea of a disability which is recovered from as soon as the pathogenic idea is disposed of.

After bruising his back by a fall from a car, a railroad brakeman remained for six months very lame; and the sensibility of the lower limbs appeared to be lost. His tint had become sallow, and he was dyspeptic and emaciated; he was sleepless, sad, and cried much. The neurological examination reported with the case (Medical Record, Oct. 2, 1909) showed that there was no destruction of the nerve elements. The disability was shown by psychoanalysis to be a function of the false fixed idea, induced by the belief derived from his environment that such symptoms as he showed could and should follow such injuries as he had had. One sitting sufficed to begin the correction of this false notion; and he himself completed the persuasion, and was able to return to work in a month, as I had predicted.

Now, the suggestibility of children is much more labile than that of such cases as I have cited; for, while they are very susceptible to suggestions, they do not usually hold them tenaciously, and are easily diverted from their loosely fixed ideas when morbid. For instance, it is perhaps unique for a girl so young as eleven to believe that she is utterly unable to eat, and to do so strongly enough and long enough to overcome the instinct of hunger to such an extent that she had to be removed for treatment to the hospital, where in the Salle Pinel of the Salpetrière Professor Déjérine built up her emaciated body by generous feeding, and at the same time undid the false notion she had acquired from her elder sister who had been a patient in the same place.

Now, this form of gastropathy from a false fixed idea is common enough in pubescent girls.[10] The origin of the idea is closely associated with the false shame of nubility, which is largely a product

of the suggestions of prudery. The medicosociological import of false shame is now being realized, I am glad to say, by enlightened educators; and it is high time. The obsession not to eat is only one of its numerous forms; but the principle of induction is the same in each; so I need not enlarge.

A much commoner type of hysteria in childhood is the imitative grimace and trick-of-manner which a child is suggested to do sometimes almost unconsciously. Thus, a choreic child may infect, with one or other of his movements, half the children in the schoolroom; and in some of the cases these movements may persist for a considerable time, and may even lead a doctor unskilled in neurological signs to believe that a child has the organic disease known as Sydenham's chorea. Nowadays we have a clear understanding of the differentia between a morbid movement arising from a perturbed nervous system and that type of morbid movement which is a function merely of idea.[11] The latter we term psychogenic.

I have chosen two conspicuous types to illustrate the genesis of hysterical ideas in order to illustrate the mechanism strikingly; but far commoner are the eventualities exhibited every day in the nursery and schoolroom. What is more familiar than the constant suggestion to a boy that he should not cry when hurt, and that he should fight with his fists when attacked? That this is not innate is shown by the repugnance of the Teutonic peoples to fistic encounters. Because it was not realized that the distaste for fistic encounters was not a mark of cowardice, but arose purely from a social suggestion of its unseemliness, the Boers, before the war with the British, were supposed to be cowards. A boy having this repugnance to personal encounter might very quickly become obsessed by the fear of its need if sent into an environment where fighting was often required.

We must now pass to consideration of induced morbid fears in children. They are, alas! very common. I need not enlarge upon the familiar fear of the dark too often induced by nursemaids' tales of bogies and ghosts. The fear of the policeman is inconsiderately used by the mothers of the poor who are too lazy, ignorant, or tired, to understand or control their children. No morbid affect usually proceeds from these, because the idea is not often implanted with enough insistence or dramatic power; but when the impression is powerful, or when the child is unduly susceptible, a suggestion, fear-psychosis is established with great facility.

It must be remembered that explicit utterance is not essential for the conveyance of ideas; for in the child a vague general notion is quite as effective for producing emotion as is a clear-cut concept. Thus in Henry James' novel, "What Maisie Knew," the whole suggestion conveyed by the governess to her two charges was implicit in her general attitude, for until the end there was not one explicit statement of her fear. Now, the explanation of this is very simple; it depends upon the fact that gesture precedes speech as a vehicle of thought. The infant comprehends the varying attitudes and vocal tones of its mother long before it can distinguish different words; and in most people this channel of information remains an important mode by which they are influenced, often quite unconsciously. Those of us who have studied the psychology of crowds are well aware of this, as likewise are the observers who compare nation with nation as regards gestural expression. Even adults of the same race, except the more cultivated, are swayed by a comedian much more through his gestures and intonation than by his actual utterance. So with an orator or debater, or, indeed, anyone who tries to persuade us, even to purchase something from them, our foolish minds are guided by the stress of an intonation, the cut of the hair, the character of the clothing, the glance of the eye, far more than by the arguments used or the words uttered, and with children this is far more so.[12]

If I say to a small boy that a bear will eat him up, the effect upon his emotions entirely differs whether I make the remark with portentous gravity and horror, or whether I say it with bubbling joviality, as evidently a huge joke. In the first eventuality, the boy will rush to my side in terror and try to be saved from the bear; and a phobia is in course of construction; with the latter procedure, the boy will laugh consumedly, and it would not take much to make him enter the cage and strike the bear. But even when terrified, a child feels a refuge in the protection of his elders during the day when they are rarely absent.

Night Terrors.—At night, however, the child is alone, and his little consciousness cannot find the easy support of others. Before the kaleidoscope of his dreams pass the various images and accompanying emotions of his waking life, so that if any of these images has become linked with fear, it is certain to bring with it terror, as it surges into dream in the night, and the child jumps up, awakened, in panic, finding no one near him upon whom to lean.

It should not be difficult to see that these night terrors are the product of a suggestion while awake, implicit or explicit. It should not be difficult for those who are forewarned to prevent morbid fears of this type.[13] I may cite the case of a Southern lady who could never enter a dark place without feeling an indescribable horror. No hereditary psychopathy could be invoked to explain her dread, for none of her three daughters had the least fear of the dark, and, indeed, they used to be sent by their school fellows into dark and eerie places without experiencing the least trepidation. The difference was that as children they were protected by their mother from the tales of the plantation negroes, who knew that dismissal would follow transgression of the prohibition.

The formation of a night-terror was nipped in the bud in the case of my own boy, then aged three and three-quarters. I shall try to explain the method. For several weeks he had been visiting the zoological garden every afternoon, in the company of a French maid of exceptionally forceful character, and apparently free from the superstitiousness of the average nurse. For a long time all went well, until one evening the boy began to cry in bed soon after he was left for the night. At this unusual occurrence, I mounted the stairs and inquired the cause of the boy's trouble. He said there were lions in the house, and that he did not want to stay alone, as he was afraid they would eat him. The source of the idea had been that the lions had roared more loudly than usual on that particular afternoon, and he had been much impressed, standing for some time quite motionless before the cage, though unterrified. I soon convinced the boy that the lions had to remain in their cages, and could not get out, hence there were none in the house, so that there was no occasion for fear. Of course, it was first necessary to give him the feeling of security gained by embracing me, and secondly to begin the conver-

sation by talking of something else, I have forgotten what. In this way the state of terror was dismissed, and the feeling of protection was induced before we returned to the subject of the lions; then we made rather a joke of the funny roaring of the lions before we had finished, and he finally lay down with solemn purpose to go to sleep and think, as I suggested, of the tramcars and motors passing outside his open window. It was all a very simple substitution, but it was the prevention of what might have become a serious fear-psychosis if injudiciously handled.

A fertile source of hysterical states, of obsessions and phobias, and of "anxiety neurosis," as he has termed it, is attributed by Freud, of Vienna, to sexual results occurring in early childhood. To the universality with which some of Freud's too ardent followers in America ascribe this cause to every psychoneurotic condition, I desire to invoke a skeptical attitude until such time as the genesis of psychoneurosis in children has been more widely investigated by judicially minded observers who are not wedded to an exclusive theory. It is to pediatrists and psychologically trained educators of the abnormal child that we must perhaps look for a large part of the data needed to decide what are the more common mechanisms concerned.

From the cases I have cited, and their discussion, I hope I have made clear one of the aspects of hysteria, and that you will comprehend the rôle of ideas induced by suggestion as producers of hysterical obsessions and phobias. The thoughtful hearer, too, will deduce from our facts the means of prevention and cure of such induced suggestion-psychoses as we have discussed. He will further perceive the importance of these psychological mechanisms as factors in the production of many a case of what is believed to be an abnormal child; and a knowledge of the principles we have discussed may enable him to displace that child from one of the categories of abnormality as laid down by Groszmann, Decroley, and others, and to replace what seemed a morbid child among those who are happy and normally useful, so that the little one may cease to be numbered among those who are called "exceptional children."

AN UNUSUAL CASE OF CONGENITAL ABSENCE OF ANUS AND LOWER END OF RECTUM.

By JOSEPH WIENER, M.D.,

NEW YORK.

ADJUNCT SURGEON, MT. SINAI HOSPITAL.

The following case is reported on account of the unusual character of the deformity and because the infant recovered from a coeliotomy performed on the first day of life, a most unusual occurrence.

Infant Brookman, one day old, admitted December 15, 1909. Since birth of infant, twenty-four hours before admission, no meconium had been passed. On examination the parents failed to see an anus and the child was brought to the hospital.

Physical examination.—The patient was a well nourished newborn infant, with slight icterus neonatorum and the head markedly dolichocephalic. Both ears are slightly deformed. The lobule of the right ear is deeply furrowed by the projection of two hard spherical protuberances, each about two millimeters in diameter. Just in front of the tragus of the left ear there is a pedunculated firm tumor, also

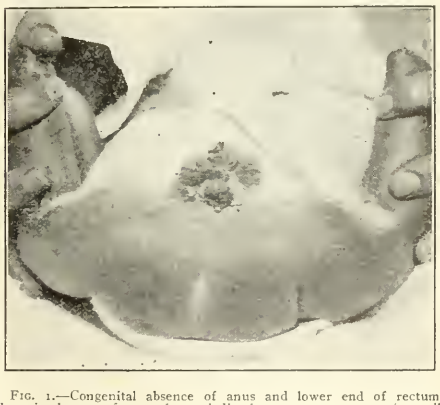

Fig. 1.—Congenital absence of anus and lower end of rectum; there is absence of even the anal dimple; one can see a cystic swelling posterior to the scrotum, which ended in a blind sack.

about two millimeters in diameter. Above the tragus there is a firm enlargement similar to the growth on the right ear. The mouth is normal, as are the heart and lungs. The liver can be felt just below the free border of the ribs, the spleen is not palpable. No lymphatic glands are enlarged. The skin on the palms of the hands and the soles of the feet is very thin, blue, and scaly. The ischiorectal region is shown in Figure 1. There is no trace of an anus, not even an anal dimple. The two halves of the scrotum are widely separated, both testicles being present, and projecting between them there is a cystic swelling one cm. in diameter. This swelling can be invaginated and when this is done the finger seems to enter a cavity.

Immediate operation December 15, 1909. Without anesthesia the cystic swelling posterior to the scrotum was incised with the expectation of finding the lower end of the rectum. However, it was found to end blindly and no trace of rectum was seen. A second incision was then made from the tip of the coccyx forward in the median line to meet the first incision. The perineal muscles were found fairly well developed. The dissection was rapidly ad-

vanced to the depth of the perineum, but no sign of rectum was found. The child was now given ether and a one and a half inch incision was made through the lower left rectus muscle. The small intestines were found collapsed. The descending colon and sigmoid were found moderately distended. The gut was found to end in a blind pouch in the midsacral region. With the half hand inside of the abdomen this lower end of the rectum was forced down into the perineal incision. The assistant then, by firm digital pressure upward, created an opening through which the operator forced down the gut. The gut was caught with clamps and opened with the immediate discharge of several ounces of meconium. The laparotomy wound was closed with through and through sutures of chromic gut, the skin with silk sutures. The opened gut was anchored to the perineal integument with four or five silk sutures. The remainder of the perineal incision was closed with

Fig. 2.—The infant shown in Fig. 1, six weeks after operation.

interrupted silk sutures. The entire operative procedure lasted thirty-five minutes, during the first part of which no anesthetic was given. On admission the child weighed six pounds, the temperature was 100.8° F. After forty-eight hours the temperature dropped to normal and remained normal for two months. During these two months we had great difficulty in feeding the child. There was a slight superficial infection of the abdominal wound, perineal wound healed rapidly. On February 15 the child developed a left otitis media, requiring paracentesis. For a week the temperatures were high, then gradually became normal and remained so. The child did not begin to gain weight until after the otitis media. On February 26 the child's weight was still six pounds. Thereafter it gained steadily until March 26, when the child was discharged, weighing eight pounds and three ounces.

46 East Seventy-eighth Street.

Typhoid Meningitis.—Claret and Lyon-Caen distinguish those cases as typhoid meningitis in which the typhoid bacillus is found in the cerebrospinal fluid in pure culture. It comes on suddenly, in general, in the course of an attack of typhoid of the ordinary type rarely with convulsions. The pathological anatomy is that of ordinary typhoid meningitis. The fluid is purulent or hemorrhagic. The convolutions are congested and glued together with exudate. There is less lesion of the nervous substance than in other types of meningitis, and only slight proliferation of the nerve cells. It may come on in the beginning, or at a later period of the disease. The diagnosis is somewhat difficult. Only examination and culture of the cerebrospinal fluid will make the diagnosis certain. Albumin in the fluid is positive. The agglutinating power of the cerebrospinal fluid with the Widal reaction, when positive, is of the greatest diagnostic value. The prognosis is relatively benign. The treatment involves hot baths, lumbar puncture, and the ordinary treatment of meningitis.—*Gazette des Hôpitaux.*

Desiccated Culture Media.—E. T. Thompson has experimented along this line. He says that the preparation of small quantities of culture media is always a tedious process and usually attended with unsatisfactory results. It occurred to him that many of the culture media might be dried and reduced to a powder containing all the requisite solid constituents which would remain indefinitely in an unaltered condition. Investigators who only have occasional use for culture media could prepare a stock on a workable scale, dry the medium, and then keep it indefinitely, weighing out sufficient quantities for a few tubes or plates as required. He heretofore determined to inquire into the practicability of such a method of preparation, and have obtained the following results by using culture media which had been subjected to the process of desiccation. The culture media under investigation were nutrient gelatin, nutrient agar-agar, nutrient beef broth, and MacConkey's neutral-red bile-salt lactose agar. These were all evaporated to dryness and when made up to their original volumes with distilled water, and dissolved at 100° C., were quite clear, the gelatin, agar-agar, and bile-salt agar solidifying with their original firmness on cooling. The reaction of the broth before drying, which was + 15 acid to phenolphthalein, remained unaltered after treatment. The agar-agar, gelatin, and broth were each distributed into test-tubes and sterilized; they were then inoculated with several of the pathogenic, saprophytic, and chromogenic bacteria, respectively, and without exception, vigorous and typical growths were obtained. The neutral-red bile-salt agar was distributed in Petri dishes and allowed to dry in the usual manner and then inoculated on the surface with a mixture of *Bacillus typhosus, B. coli, B. subtilis,* and *B. megatherium* by means of a bent glass rod. No difficulty was experienced in rubbing the surface with the glass rod; in fact, the rubbing was performed a little more vigorously than necessary in order to test the texture of the medium, but it remained unbroken. After forty-eight hours' incubation at 40° C. typical colonies of *B. coli* and *B. typhosus* had developed, the coli colonies being red and the typhoid colonies being colorless. The *B. subtilis* and *B. megatherium* had not grown. The foregoing experiments show that the typical reactions may be obtained with this medium after desiccation and that its inhibitory properties are in no way impaired. —*The Lancet.*

Myelogenous Leukemia Following Pancreatic Cyst.—Barker reports a man aged twenty-eight years. Fourteen years before he was operated upon for a pancreatic cyst, following an injury. The cyst was opened and drained, and recovery was complete. The patient was well until three months ago, when he noticed abdominal discomfort. Three weeks ago he noticed swelling of the left side of the abdomen, which proved to be a large spleen. The blood count was as follows: Red cells, 3,600,000; leucocytes, 77,700; hemoglobin, 30 per cent. There were 28 per cent. of myelocytes. After ten days' treatment with arsenic and iron, the red cell count was 4,840,000, the leucocytes 42,000, and the hemoglobin 45 per cent. Nucleated red cells were numerous.—*Proceedings of the Royal Society of Medicine.*

Radiumtherapy.—L. Chevrier says that there is good evidence that radium has a stimulating effect on the tissues of wounds causing increase of granulations and rapid cicatrization. He has treated wounds of various kinds with pomades and radiferous powders with good success. An inert powder is mixed with radioactive powder and applied to the wound under a loose gauze dressing. It causes, at first, an abundant secretion, similar to that following fulguration, but containing no pus cells; active granulation then takes place, and epidermization of ulcers and wounds goes on much more rapidly than ordinarily occurs. Atonic ulcers cicatrize as well as healthy wounds. The author gives illustrative examples. He is now making experiments with flesh colored powders, with which he will tattoo the cicatrices to render them more normal in appearance. This is rendered possible by the rapidity of granulation which takes place, such that small granules are enclosed and remain permanently in the cicatrix. —*Le Progrès Medical.*

MANDELBAUM'S REACTION IN THE DETECTION OF TYPHOID CARRIERS, AND IN THE DIFFERENTIATION OF TYPHOID FEVER.

LAST winter Mandelbaum published an account of his so-called "fadenreaction," which may possibly come to be regarded as a test of considerable value in connection with the persistence of virulent typhoid bacilli in individuals who once suffered from the disease. In its practical bearings a rough similarity with Wassermann's seroreaction in old syphilitics will be remarked; although the latter test rather shows that a person once had syphilis, than that he necessarily still has it, since while parasyphilitics commonly give very high percentage of positive Wassermann tests, yet they cannot be said to suffer from virulent syphilis in any sense of the word; they cannot communicate the disease, nor are they amenable to specific treatment.

There is an alleged difference in the Mandelbaum reaction as to recent and past typhoid. In the recent case, with a drop of blood transferred to a suitable medium which is slightly inoculated with typhoid bacilli, the latter exhibit a marked tendency to arrange themselves in chains or threads (hence evidently the term "faden" reaction), or else in clusters. All the bacilli are alike immobile. This phenomenon in itself is said not to be present in any other form of disease, for the typhoid bacilli remained isolated and movable in all others tested. The blood of a person who years before had passed through typhoid gives both chains and clusters of immobile bacilli, but a certain number remain isolated and movable. Mandelbaum found that at any period within twenty-four years this reaction was obtainable in old typhoids. The similarities and differences between the fadenreaction and the ordinary agglutination test are at once partly apparent, but a comparison of the two cannot be instituted in this connection.

Gaehtgens and Kamm have reported on the fadenreaction in the *Münchener medizinische Wochenshrift* for June 28. They regard it as less trustworthy for the detection of a bacillus carrier than the opsonic index, for elevation of the latter is practically constant in a carrier, while the fadenreaction was often absent in 25 per cent. in these subjects. In the cases of fourteen known carriers the ordinary agglutination test proved useful in eleven, but of no value in the remainder. The fadenreaction did not seem to confer any greater degree of certainty. There were two negative results, while as in the agglutination test, the positive findings were not always typical and conclusive. Thus in regard to the mobility of individual bacilli, this was present or absent almost indifferently; and of two patients each infected three and one-half years before, one showed mobility, the other immobility. Several infected many years ago showed mobility in accordance with Mandelbaum's claim. But for that most interesting class of carriers, viz., those who apparently never went through the fever at all, three showed mobility and two immobility. Mandelbaum also insisted on the value of his reaction in distinguishing typhoid from paratyphoid and other pseudotyphoids. The authors conclude in this regard that when the "positive" finding is sufficiently characteristic it possesses some specific value (it was, however, present in two paratyphoid cases). Unfortunately, however, many so-called positive results are incomplete, or in other words dubious, and so possess no specific worth. A good positive result with an unsatisfactory agglutination test should be of value, but such a coincidence did not appear. On the contrary the most positive results gave the highest agglutination figures. While the authors do not commit themselves as to the future value of this test, they appear to regard it as an interesting development of serodiagnosis, but admit that the material upon which it was tested was not large.

PRESENT STATUS OF AURAL SURGERY.

IT is generally admitted that comparatively recent advances in aural surgery—practically middle-ear surgery—have been the means of saving many lives. Not so very long ago an intracranial infection from a middle-ear focus almost invariably ended fatally. But even as much has already been done, so much of the same sort still remains to be done in timely diagnosis or rather prognosis of middle-ear infections, as to their likelihood of causing intracranial infection; and in timely and suitable surgical intervention.

Professor Heine recently delivered an address on the present status of aural surgery, which appears in the *Münchener medizinische Wochenschrift* for June 21, and is accompanied by some discussion on the part of the society members before whom it was read, who are a body of general practitioners. Chronic otitis media with perforation should always be treated conservatively at first; but after conservative measures have failed the lecturer would proceed to radical operation, despite the quiescence or "coldness" of the process. Whenever an acute exacerbation occurs, or there is an extension threatened to the mastoid cells or labyrinth, the indication to operate becomes urgent. The recognition of labyrinthine extension has now become easy, and the surgeon is no longer taken unawares thereby. Nor does he nowadays fear to open and drain the labyrinth, a procedure which not only prevents meningitis but checks it if it is already developing.

Much has been learned as to the diagnostic significance of temperatures in otitis media, in their bearing on the question of surgical intervention. Fever, even mild, in a cold middle-ear suppuration—when all other sources of temperature rise may be excluded—is always a serious development, and warns us of the proximity of a meningitis or pyemia, the latter usually manifested by an infection of the transverse sinus. Hence, if such fever appears, we should first examine for possible meningitis, and if this is excluded, we have an indication to lay bare the transverse sinus. This done, we may usually proceed on the expectant plan, as the drainage afforded by exposing the sinus is often sufficient for recovery. If the case does not progress favorably, as shown by the persistence of fever and evidence of thrombus formation the sinus must be punctured and the clot removed. If the thrombus has become infected, the sinus must be curetted and some of its wall may require extirpation. Ligation of the jugular vein is not required as a routine procedure, but only when the case has, generally speaking, got beyond control. It must also be borne in mind that ligation or partial extirpation cannot invariably prevent pyemic infection, for the latter may occur by the retrograde route.

The developments of aural surgery are naturally known to all specialists, but the character of the advances in diagnosis and surgical procedure is often such as to place a powerful resource into the hands of the general practitioner with surgical leanings, when confronted by emergencies. He, at least, should spare no pains in becoming familiar with all such advances, for in many cases the indications will be so obvious that he can avoid the dangerous delays involved by consultations.

Fixation Abscess for Chronic Lead Poisoning.

Readers of current medical literature for the past dozen years have doubtless seen occasional reference to the treatment of various conditions by establishing an artificial abscess at a distance, and have probably thought in this connection of a revival of the old seton or issue, with its *raison d'être* of drawing bad pus or humors out of the system. For a considerable period most of the clinical reports of the use of fixation abscesses seemed to proceed from one or more provincial French clinics, and the conditions in which they effected alleged cures, such as protracted puerperal sepsis, were those for which so many other remedies have been vaunted; or such as might at times benefit by any plan of counter irritation. Hinze of St. Petersburg (*Berliner klinische Wochenschrift*, June 27) touches on a special possibility in connection with the benefits of artificial and controlled suppuration, to wit, that certain mineral poisons may actually be conducted out of the system by this means. Quite recently Carles and Arnozan showed that leucocytes may be active agents in the elimination of certain drugs. Tested on a case of chronic plumbism it was found that 32 grams of such pus contained 0.0025 gram lead in the form of sulphate. This case and another of the same kind were believed to be the only ones on record until Hinze treated a patient more from clinical than experimental motives. In all he caused his patient to lose during four weeks a large amount of pus, which always contained lead sulphate. The percentage of the latter rose as treatment progressed. The patient appeared to improve under treatment, but as he was badly affected with arteriosclerosis, interstitial nephritis, myocarditis, and lead encephalopathy there could be no hope of recovery. The patient, who had already suffered a stroke of apoplexy, soon developed a second and fatal attack. The liver was tested for stored lead, but only a mere trace was found. It looked as if the lead had been removed from storage by the leucocytes. The abscesses were set up by injecting turpentine beneath the skin of the thigh. The rationale of using these abscesses in pneumonia, sepsis, etc., is based on the belief that the toxins of the disease may be thus removed. The process has some prognostic value; for the pus should form in twenty hours, and its failure to appear is ominous. The pus formed should be sterile—so-called chemical pus; and it is claimed that the treatment is well-borne and innocuous. There is no allusion to the possibility of amyloid degeneration.

The Spread of Bovine Tuberculosis.

Professor Sheridan Delépine of Manchester contributed an article to the *Lancet* of May 14, in which he gave the results of studies recently undertaken by him, in regard to the influences determining the prevalence of bovine tuberculous mastitis. Although the evidence so far has shown that bovine tuberculosis is, on an average, more prevalent in a district where cowsheds are generally in a bad state, small, badly ventilated, or dirty, it has not demonstrated that these are by any means the sole causes. Ordinary sanitary measures will not control bovine tuberculosis. Cows with ulcerating lesions, *i.e.* cows in the actively infective stage of tuberculosis, are capable of emitting and do emit an extraordinarily large number of tubercle bacilli. Ordinary sanitary measures are of little avail to control the spread of the disease by animals in such a condition. Delépine concludes that bovine animals suffering from ulcerative tuberculous lesions, more especially of the respiratory organs, alimentary canal, genito-urinary organs, and udder, constitute the chief factor determining the prevalence of bovine tuberculosis. This conclusion indicates the great importance of inspecting every animal, of removing without delay all those that are actively infective, and of not allowing healthy animals to remain in places that have been infected, so long as these places have not been thoroughly disinfected. All animals affected with tuberculosis are potentially dangerous, and as their age advances the chance of their becoming actively dangerous increases. Consequently it is desirable to reduce as much as possible the number of old animals. After all, the only way to stamp out tuberculosis in cows is to destroy those affected with the disease in a dangerous degree and to segregate those that have the disease in a milder form.

A Marine Floating Laboratory for Tropical Research and Teaching.

A scheme is afoot in Great Britain to establish a large school of tropical medicine in Calcutta. Dr. Andrew Balfour of the Wellcome Tropical Research Laboratories, attached to the Gordon Memorial College, Khartoum, writing in the *Lancet*,

July 2, applauds the idea and goes on to suggest the establishment of a marine floating laboratory for Great Britain. In connection with the Wellcome Laboratories in Khartoum there is a floating laboratory on the Nile, and it is because this laboratory has been so conspicuous a success that Dr. Balfour has mooted the imperial floating laboratory idea. He proposes that a ship of 800 or 1000 tons should be fitted for the purpose. Such a ship would be able to visit any portion of the globe, could ascend large navigable rivers, and would be the means of bringing back a store of most valuable material, both for museum and for teaching purposes. Furthermore, it would be the duty of whoever was placed in charge to conduct abroad the best students in tropical medicine of the year. There can be little doubt, too, that many graduates would welcome the opportunity for such a course of study, as facilities would be given to visit tropical hospitals and laboratories in different countries. These institutions are often in cities on or near the sea and it is on the litorals of tropical countries that most of the diseases peculiar to the torrid zone occur. It is plainly apparent that the consummation of the plan suggested by Dr. Balfour would have the effect of advancing our knowledge of tropical diseases and would be a benefit to humanity at large. If the necessary funds to carry out the proposition cannot be found in Great Britain, there would seem to be no insuperable objections to making it an international affair.

News of the Week.

City Death Rate.—During the week ending July 23, the death rate in New York was 17.18 per 1,000 of population, an increase over last year when the rate was 16.17. The total number of deaths was 1,552, or 122 more than for the same week of 1909. Among children under five years of age there were 694 deaths; among children under one year, 523; 389 of these deaths were ascribed to diarrheal diseases. There were 674 deaths in tenements and 582 in institutions. Scarlet fever caused 9, pneumonia 106, and tuberculosis 54. Seventeen persons died from sunstroke, and 130 from violence. The rather high death rate in the city, particularly among young children, during July, has led to an interesting comparison with the figures of previous years by the officials of the Department of Health. During the years 1908 and 1909 the general death rate in July reached low figures in comparison with other years, figures which have unfortunately been exceeded during the past month. In 1908, the highest rate was 18.50 for the week ending July 25, and in 1909, 16.96 for the week ending July 30, while for the week ending July 16, 1910, the rate was 18.88. The difference is more marked in the comparison between the death rates of children under two years of age during three weeks of July in 1909 and 1910, which were as follows:

MANHATTAN.

	July 10.		July 17.		July 24.	
	Deaths.	Rate	Deaths.	Rate.	Deaths.	Rate.
1909	61	28.13	80	37.1	172	51.9
1910	108	46.00	181	92.1	190	85.8

BROOKLYN.

	July 10.		July 17.		July 24.	
	Deaths.	Rate	Deaths.	Rate.	Deaths.	Rate.
1909	72	51.00	123	87.0	144	102.0
1910	127	87.4	167	114.9	114	78.4

CITY.

	July 10.		July 17.		July 24.	
	Deaths.	Rate	Deaths.	Rate.	Deaths.	Rate.
1909	159	38.0	239	55.2	306	73.0
1910	266	61.6	424	98.2	373	86.4

The years 1908 and 1909 were, however, exceptional, largely, as the MEDICAL RECORD pointed out at the time, because the population of the city was assumed to be much greater than it really was. In 1907, the death rate for six successive weeks, from July 13 to August 24, was higher than the highest figure recorded so far this year, and in 1905 the rate rose to 28.00 for the week ending July 22. During that week 1,073 babies died in the entire city. The highest general death rate in recent years occurred in the week of July 6, 1901, when the figure was 40.82 per 1,000. During that summer, which was one of more than tropical heat, the death rate for twelve successive weeks was considerably above the highest figure so far recorded in 1910. The Department of Health ascribes the high death rate among babies in hot weather to the ignorance of the mothers, and for their edification has issued a simple list of rules for caring for infants, printed in several languages, and urging that prompt notification of illness be sent to the branches of the Department. The mortality among babies is found to be highest among the negroes, the Italians ranking second, and the Russians third. The Yiddish-speaking population of the lower East Side has a comparatively good record.

Immigration Statistics.—Immigrants to the number of 1,041,570 were admitted into the United States during the last fiscal year. Italians had the largest representation, 223,453; and Koreans the smallest, 19. The Jewish immigrants numbered 84,260; the Germans, 71,380; the English, 53,498; the Irish, 38,832; the Magyars, 27,302; African negroes, 4,966; Japanese, 2,798; East Indians, 1,782; Chinese, 1,770. During the year 156 idiots, imbeciles, and feeble-minded, 160 insane, and 2,471 persons with chronic or contagious diseases were debarred.

State Board of Pharmacy.—According to an opinion issued by the Attorney-General, the members of the New York State Board of Pharmacy will hold over in office until the State Regents appoint a new board in accordance with Chapter 422 of the Laws of 1910. The new law, which makes radical changes in the number of the members of the board, their method of selection, and their tenure of office, provided that the term of office of the present board of nine members should expire on August 1, and that the fifteen new members should take office on that day. So far the Regents have failed to appoint a new board, and it is now unlikely that they will do so until next September.

Cholera in Russia.—Figures given out by the Russian Government Sanitary Commission recently show that since the outbreak of the cholera epidemic, about the middle of May, until the end of July, 37,652 cases occurred with 16,651 deaths. The entire region affected includes forty-two provinces and territories. In the week ending July 23, 13,374 cases were reported, with 5,979 deaths.

Street Car Accidents.—During the month of June, 27 persons were killed and 232 seriously injured in accidents on the city transit lines in New York, according to the report of the Public Service Commission. In June, 1909, the figures were 30 killed and 211 seriously injured, and in June, 1908, they were 42 and 302 respectively.

Tuberculosis in the Philippines.—Secretary of War Dickinson, who is now visiting the Philippine Islands, assisted on July 29 in the organization of a national society for combating tuberculosis in the islands. The disease is said to have become alarmingly prevalent among the Filipinos.

Foot and Mouth Disease.—Owing to the outbreak of foot and mouth disease among the cattle in Yorkshire, England, the United States Department of Agriculture has prohibited the importation of cattle from that country for the present. The same action has been taken by the Canadian Government. The extent of the infection has not yet been determined, but the embargo will be strictly enforced until the authorities are satisfied that the disease has been stamped out. Most of the cattle imported into this country for breeding purposes come from the Channel Islands which have not been placed under the quarantine.

Sewage Disposal.—Plans for the disposal of the sewage of the city of Rochester, N. Y., by discharge into the waters of Lake Ontario, were recently returned to the State officials by Health Commissioner Porter without his approval. The pollution of the Genesee River has reached a point which makes it necessary for the city to dispose of its waste in some other way, but after consultation with sanitary engineers the Commissioner has decided that the present plan does not provide for sufficient treatment of the sewage. When a more complete system of disposal is mapped out the plan for using Lake Ontario will probably be approved.

Ambulance in Collision.—While answering a call on July 26, an ambulance of the German Hospital, Williamsburg, N. Y., was struck by a trolley car of the Myrtle Avenue line. Both the surgeon, Dr. Edwin A. Spies, and the driver of the ambulance were injured.

Dr. Richard C. Newton of Montclair, N. J., has received the Democratic nomination for mayor of that town.

Dr. Glenworth R. Butler of Brooklyn, N. Y., has been appointed a member of the State Board of Medical Examiners for the term of three years.

Enforced Cleanliness.—A list of eleven regulations issued by the Health Department of Aurora, Ill., and designed to improve the health of the community, includes one making a weekly bath compulsory for each resident. The Health Officer and the Chief of Police are quoted as saying that the ordinance will be strictly enforced and that violators will be arrested and punished to the full extent of the law. The developments promise to be interesting.

Dr. Leonard Wood has recently assumed his duties as Chief of Staff of the United States Army.

Censure Insane Asylum.—The Newark, N. J., Grand Jury recently returned a presentment criticising the management of the Essex County Insane Asylum, at Overbrook, and recommending the removal of the superintendent of that institution. The presentment also recommends that the Board of Freeholders be relieved of the care of the asylum, and that it be placed in the hands of a competent board of managers, or under State control.

The Antivivisectionists.—A recent order authorizing the poundmaster of the city of Washington to sell dogs picked up on the street to the Bureau of Animal Industry "for research work" caused a small tempest among the antivivisectionists. The Acting-Secretary of the Department of Agriculture explained, however, that the dogs were to be used in the investigation of the disease among sheep known as "gid," due to a parasite conveyed by wolves and dogs, giving it as his opinion that the dogs would come out of the experiments "in better health than they went in." The report of an interview with Mrs. Diana Belais is a fair sample of the exaggeration in which the supporters of the antivivisection movement habitually indulge. Mrs. Belais is quoted as saying that "It is a most shameful and disgraceful state of affairs to think that the United States Government should become a party to such cruelty. There can be nothing more debasing to its people than such a showing of wanton cruelty; and it is horrible to think that the Government, through its unthinking officials, should set up a standard for gross cruelty." It would of course be expecting too much of the antivivisectionists that they should acquaint themselves with the facts before attempting to state them.

Population of Oklahoma.—The census returns for Oklahoma give the State a population of 1,651,951, lacking the returns from three districts which will, however, affect the total by only about 5,000. This means an increase in population of 16.8 per cent. since the special census taken less than three years ago, and of 109 per cent. since the census of 1900.

Bequests to Charities.—St. Francis Hospital, New York, receives $1,000, and the Free Cancer Hospital, Hawthorne, N. Y., $500, under the will of the late Mary P. McLoughlin of New York.

The will of the late Adolph Leberman of Philadelphia contains the following bequests to charitable institutions of that city: Jewish Foster Home and Orphan Asylum, $350; Home for Incurables, $250; Jewish Seaside Home, $200; Children's Homeopathic Hospital, St. Christopher's Hospital, and Mt. Sinai Hospital, $100 each.

American Association for Study and Prevention of Infant Mortality.—The first annual meeting of this association will be held in Baltimore on November 9 to 11, 1910, under the presidency of Dr. J. H. Mason Knox of Baltimore. Dr. L. E. LaFetra of New York is the secretary of the society. The work of the association will be divided into sections on Municipal, State, and Federal Prevention, Dr. William H. Welch, *Chairman;* Medical Prevention, Dr. L. Emmett Holt, *Chairman;* Educational Prevention, Dr. Helen C. Putnam, *Chairman;* Philanthropic Prevention, Dr. Hastings H. Hart, *Chairman.* A special report on birth registration will be presented by Dr. C. L. Wilbur, Chief of the Division of Vital Statistics of the Bureau of the Census.

American Association of Obstetricians and Gynecologists.—The twenty-third annual meeting of this association will be held in Syracuse, N. Y., on September 20 to 22, 1910, Dr. Aaron B. Miller, President. Dr. Albert E. Larkin of 509 Genesee street, Syracuse, is chairman of the committee on arrangements.

The Rhode Island Medico-Legal Society.—At the annual meeting of this society, held on July 21, the following officers were elected for the ensuing year: *President,* Dr. Arthur H. Harrington; *Vice-President,* Benjamin W. Grim; *Secretary-Treasurer,* Dr. Carl R. Doten; *Censors,* E. H. Lincoln, Dr. E. P. Stimson, Dr. C. S. Christie, Dr. J. H. Morgan, Dr. C. W. Stewart.

Obituary Notes.—Medical Director James A. Hawke, U. S. N., retired, died at the Naval Medical School Hospital in Washington, D. C., on July 25, aged 69 years. Dr. Hawke was graduated from the medical department of the University of Pennsylvania in 1861, and during the Civil War served as assistant surgeon in the 114th Penn-

sylvania Volunteers, and as surgeon in the 215th Pennsylvania. At the close of the war he became an assistant surgeon in the United States Navy, and was made passed assistant surgeon in 1873, surgeon in 1879, and medical inspector in 1895. In September, 1899, he was appointed medical director, and was in charge of the Naval Hospital at Mare's Island, Cal., until 1903, when he retired with the rank of Rear Admiral.

Dr. C. H. Smith of Arcadia, Fla., died recently at Candler, N. C., following a stroke of paralysis. Dr. Smith was born in 1855, and was graduated from the Atlanta Medical College in 1880. He was a member of the State and county medical societies.

Dr. William C. Baylor of Willows, Cal., died in Sacramento following a stroke of paralysis, on June 27, aged 67 years. Dr. Baylor was graduated from the College of Physicians and Surgeons of Baltimore, Md., in 1869.

Dr. Ernest C. Blake of Boothbay Harbor, Me., a graduate of the Dartmouth Medical School, Hanover, N. H., in the class of 1892, died suddenly at his home on July 8, aged 41 years.

Dr. William W. Easton of Dowagiac, Mich., died at his home on July 14, after a long illness. He was graduated from the Bennett College of Medicine and Surgery of Chicago in 1877, and was a member of the Michigan State and Cass County Medical Societies.

Dr. Jacob Randall, a retired physician of Okawville, Ill., died at his home on July 7, aged 85 years.

Dr. Robert S. Powell of Woodview, Va., died at his home on July 11, aged 75 years. Dr. Powell was graduated from the Department of Medicine of the University of Virginia in 1857, and was a member of the Virginia State and Brunswick County Medical Societies.

Dr. Edwin S. Cave of Mexico, Mo., a graduate of the Missouri Medical College, St. Louis, in 1884, a member of the American Medical Association and of the Missouri State and Audrian County Medical Societies, died at his home on July 10, aged 54 years.

Dr. J. B. Farley of Farley, Ala., a graduate of the Medical Department of Vanderbilt University, Nashville, Tenn., died of typhoid fever at his home on July 7, aged 50 years.

Dr. Louis R. Brown of Elizabeth, N. J., a graduate of the Homeopathic Medical College of Pennsylvania in the class of 1864, died at his home on July 18, aged 70 years.

Dr. Julius Stein of New York, a graduate of the College of Physicians and Surgeons of that city in 1885, died at his home on July 22.

Dr. Richard H. Stone of Brooklyn, N. Y., a graduate of Dartmouth College and of the College of Physicians and Surgeons, 1866, died suddenly of apoplexy on July 27, aged 73 years.

Dr. Frederick Chauncey Graves of Bridgeport, Conn., a graduate of the Medical Department of New York University in the class of 1888, a member of the American Medical Association, and of the State and Fairfield County Medical Societies, and visiting physician to the Bridgeport Hospital, died suddenly, on July 26, from an overdose of morphine, aged 47 years.

Dr. Horace F. Hanson of Bangor, Me., a veteran of the Civil War, a graduate of the Berkshire Medical College of Pittsfield, Mass., in 1866, a member of the American Medical Association, and of the State and Penobscot County Medical Societies, died at his home on July 17, aged 72 years.

Dr. Mark S. Leavy of Albany, N. Y., a graduate of the Medical Department of the University of Wooster, O., in 1888, and a member of the State and Albany County Medical Societies, died at his home, on July 20, of heart disease, after a long illness.

Dr. William J. W. Cornwell of Cornwell, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1866, and a member of the State and Chester County Medical Societies, died at his home, on July 15, aged 69 years.

Dr. William L. Forrester of Philadelphia, Pa., a graduate of the Medical Department of New York University in the class of 1881, died at his home, on July 19, aged 49 years.

Dr. Frederick W. Lilienthal of New York, a graduate of the University of Berlin, Germany, in the year 1858, and a member of the New York Academy of Medicine, the German Medical Society, and the Eastern Medical Society of the City of New York, died at his country home in the Catskill Mountains, on July 28, aged 77 years.

Correspondence.

MEDICAL COLLEGE HOSPITALS.

To the Editor of the Medical Record.

Sir: I should like to join Medical Director Coplin in reminding President Schurman that there are others among American medical colleges that have entire control of attached hospitals. I refer now especially to the Centenary Hospital attached to Barnes Medical University of St. Louis, which owns this hospital so far as its charter will permit it to be owned by any college. The Barnes holds the bonds of this hospital and its faculty direct it; its patients are conducted for clinical purposes into the college amphitheater.

I speak of this, though not now of the faculty, as one of the founders of the Barnes College and Centenary Hospital. Others can speak for other hospitals.

C. H. Hughes, M.D.

St. Louis, July 25, 1910.

POISON IVY RASH.

To the Editor of the Medical Record:

Sir: The description in the Medical Record of July 23 by Dr. R. Ellis of his sufferings from poison ivy dermatitis, and of difficulties of relief may well justify the communication of a treatment repeatedly used by the writer in former years with full satisfaction. Here in this city these cases seem exceedingly rare, and hardly ever are seen again. The treatment consists in applying two or three times a day flowers of sulphur rubbed up with sufficient water to a thin paste. Of course it should not be washed sulphur or lac sulphuris.

C. G. Am Ende, M.D.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

CANCER AND RESEARCH INSTITUTION—DANGERS OF WORKERS WITH LEAD AND IN DUSTY EMPLOYMENTS—MEDICAL SOCIETIES—PENSIONS ON CIVIL LIST—LORD STRATHMORE'S ENDOWMENT OF UNIVERSITY CHAIR—NOTES—OBITUARY.

London, July 15, 1910.

Yesterday afternoon the foundation stone of the Barnato-Joel Memorial Hospital for Cancer and Laboratory for Research was "well and truly laid" by Prince Francis of Teck, who announced that the Queen had consented to open the building next year. The building will occupy the site bought for it adjoining the Middlesex Hospital, to which, in a way, it will be an additional wing, but at the same time an independent institution. It will not only be built but endowed out of the munificent fund bequeathed by Mr. H. P. Barnato in memory of his brother and his nephew (Mr. Joel). The cancer department of the Middlesex Hospital is too well known to need more than congratulation that its work will receive this important extension,

and we may all feel satisfaction that instead of a new competing hospital, this well tried one will have both its charitable and research work so widely extended. Prince Francis, who, as I mentioned to you, has lately become chairman of the Middlesex Weekly Board, and issued an appeal for funds, said that when he did so he little knew how much work it would entail, but he does not seem to mind it, for he is zealously pushing his appeal, and remarked that opening his morning letters without knowing what was coming was as exciting as a big bet on a race course. He said, too, it was a great day for every Middlesex man, for a hospital to receive cancer sufferers is established and a research block committed to the care of eminent men whom all hope and fervently pray may be successful and come out victors against this terrible scourge.

On Tuesday the report was issued of the departmental committee on the dangers attending the use of lead, and on injury or danger to health from dust or other causes in the manufacture of china and earthenware, and in processes incidental thereto, including the making of lithographic transfers. You will see that the reference was wide, and it is not to be wondered at that the inquiry has extended over two years. Yet the committee itself scarcely considers its report exhaustive, for it informs the House Secretary at the outset that should he desire to call it together again, all the members would be ready to give him their assistance. In pottery factories some 63,000 workers are employed, and of these 6,865 are engaged in dangerous processes in contact with lead, 23,000 incur danger from breathing dust other than lead. Efforts have been made from 1894 to make rules which would put an end to the lead poisoning, but with little success. From 1901 to 1908 the number of cases remained stationary, but there was a decrease in 1909. It was suggested to the committee to draw up a schedule of articles in the manufacture of which lead should be absolutely prohibited, but though they admit the simplicity of such a solution, after full consideration of the proposal in all its bearings they do not advise this course at the present time. The public has displayed less interest in the dust problem than in lead poisoning, but the committee makes stronger recommendations concerning it, including ventilation and temperature. They would also prohibit boys and girls under 16 from carrying the clay for the work.

Dealing with women workers, they consider the lead danger, whether it appears as poisoning or increased liability to miscarriage, would be greatly mitigated if not actually removed by the strict observance of certain precautions. Otherwise women under 45 could be excluded from the most dangerous processes. Plumbism, serious as it is, is not so widespread as lung disease from labor connected with lead, like working in hot, dusty and moist rooms. New rules are proposed, but the committee cannot hope they will be effective unless they are more strictly carried out than previous rules have been. All occupiers of factories must, therefore, be made to realize their responsibilities. Miss Tuckwell, the lady member of the committee, adds a separate note urging that inspection from without is of more value than the report intimates. She would also approve a schedule of articles to be made by leadless glazes only.

Professor Osler went to Nottingham to open the new premises of the Medical-Chirurgical Society. He gave an address in the course of which he argued that a medical society ought to be a post-graduate school or a sort of clearing house of professional experience in its locality. Good pathological specimens should be exhibited at fortnightly meetings. One might interpolate here that in a small district it might be well for the populace that none had been obtained in the fortnight. It was only natural, he declared, for the doctor to think of himself last—for the profession would not be organized on a commercial basis. He could not combine the altruistic with the business sides of his work as in many other callings, though the laborer was worthy of his hire. He warned against discord and jealousy, which, he said, was often displayed by seniors to juniors, and he laid down three rules which everyone would find good to follow: (a) Listen to no tales told of a doctor by a patient; (b) Believe no tale of a doctor even if you know it to be true; (c) Tell no tale yourself, even if you are itching to do so.

Civil list pensions have been granted in consideration of services in connection with the profession to Mr. T. Bryant, Mrs. Gamgee, widow of the late Professor Arthur Gamgee, Miss H. S. Murphy, daughter of the late Professor E. W. Murphy, M.D., Mrs. Fraser, widow of the late Professor Alex Fraser, Miss Dobson, sister of the late Sergeant-Major Dobson, F.R.S.

At the graduation ceremony of the University of Aberdeen on Wednesday it was announced that Lord Strathcona had just given £10,000 to endow a chair of Agriculture with the new professor as dean, and associated with the chairs of Botany and Zoology.

The Edinburgh Royal College of Physicians has conferred the Cullen Victoria Jubilee Prize on Dr. R. W. Philip for his investigations in connection with phthisis. The award, of the value of £100, is made every four years for the most important contribution to practical medicine.

The Astley Cooper Prize has been awarded by the Guys Hospital School to Professor E. Starling, F.R.S.

Sir Alfred D. Fripp has been appointed honorary surgeon-in-ordinary to the King.

A special reserve is to be established in connection with the Royal Army Medical Corps.

Dr. Dawson Williams, editor of the *British Medical Journal*, was thrown from his motor car on Saturday as the result of a collision. He sustained a severe shock with slight concussion, but happily is progressing well and we are all wishing him a speedy recovery.

The death took place on the 11th inst. of Mr. Harry W. Cox, at the age of 46, after 12 years of suffering as a victim of his early researches in connection with Röntgen rays. You will remember that in spite of his severe injuries as a pioneer and the steady advance of the terrible lesions produced, he did not discontinue the investigations and took out numerous patents for improvements in apparatus, as well as for an invention for locating the position and depth of a bullet. But about seven years ago his sufferings drove him into retirement. He underwent several operations without arrest of the progress of the disease in the same way as his fellow-sufferer, Dr. Hall Edwards.

News has just reached London from Forcados of the death of Dr. Alfred B. S. Powell, of the West African Medical Service, "who died of syncope during the outbreak of yellow fever," a statement which looks as if he was a victim of overwork. He was only 37 years old and qualified at the two colleges of Edinburgh in 1898. He had been medical officer to Grahamstown Asylum, and held another appointment at Cape Colony before going to West Africa.

Dr. J. Hougham Bell, surgeon for many years to the Royal National Consumption Hospital at Ventnor, died on the 8th inst., aged 64. He was a King's College student and Warnsford scholar of 1863. Earlier he had given attention to mental diseases and been assistant superintendent of Northampton Asylum, but for some 30 years had practised at Ventnor.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

THE RÔLE OF RADIUM IN THE TREATMENT OF CANCER—INSTANTANEOUS RADIOGRAPHY—VACCINOTHERAPY IN ACUTE PYELONEPHRITIS OF PREGNANCY.

PARIS, July 15, 1910.

WICKHAM and Degrais, presented by Charles Monod, made a very interesting communication with reference to the position of radium in the surgery of cancer. The authors stated that radium should only be applied to the treatment of cancer under the control of the physician, and especially of a surgeon competent to decide whether the circumstances are such that radiotherapy should be employed in preference to all other methods, or whether by reason of the nature of the case, its position, or its state of evolution it would not be better to make use of some other method of treatment. Until we have discovered a remedy having a specific action on neoplastic tissues the total removal of cancer by the knife will remain the most sure and rapid method at the disposition of the practitioner. In the most of the cases in which radium therapy is indicated it is best to associate it with a surgical oneration. The action of radium is in proportion not only to the depth to which the rays penetrate, but also to the number of rays which enter at a given point. Wickham utilizes a technique which he calls "crossed fire." It consist in grouping over the region to be treated several x-ray apparatuses whose rays cross each other, to act at the same time on the diseased tissues. It is above all important that the radium should be placed in actual contact with the neoplasm, and it is for this purpose that the surgeon may with advantage operate to facilitate access to the diseased portion, as well as to reduce by a previous operation the mass of tissue in which we seek to produce regression.

Access to the diseased part may be had through the natural passages for the esophagus, bladder, rectum, uterus, etc., or through an artificial orifice such as a gastric fistula, permitting the radiferous apparatus to be carried even to cancer of the pylorus. If the action of radium is often favorable the results to be expected are never other than local. There is a long distance between the regression of a tumor and the cure of the patient. The action of radium is purely local and does not surely place the disease safe from recurrences, which must be combated anew by new applications at an opoortune time. Limited in its rôle, then, radium is a resource useful above all when it is employed under the control of the surgeon. Segond has never seen radium bring about the cure of a neoplasm. At the same time he has seen it bring about such changes in the evolution of malignant growths, cause such curious transformations and such important amelioration that in every case in which an operation is not justifiable he believes that radium is indicated.

Pierre Delbet thinks that the great advantage of radium is that it can be placed wherever we wish. His technique consists in introducing tubes of radium into the thickness of the neoplasm. He does it with a large trocar, the mandrin of which he withdraws; by the cannula he introduces the tube of radium and keeps it in place with a soft mandrin while he removes the cannula; the tube furnished with a thread is placed where it can act best. Radium appears to have a selective action on epithelial cells which it kills. The phagocytes then seize on these cells of the neoplasm which have been killed and surround them. The tumor disappears without there being any loss of substance, but the marvelous action of radium is circumscribed; it never reaches more than 25 millimeters; around the radiferous tube we find three concentric zones: a zone in which the epithelial cells are destroyed; a second zone in which their evolution seems to be modified without destruction; and lastly at the periphery a third zone in which the epithelial cells show evidence of stimulation. If the tumor regresses in the center it progresses rapidly at its periphery and this is the only danger. The only means of preventing this is to riddle the tumor with radiferous tubes in such a way that each tube extends its action beyond the apparent limits of the neoplasm. Tuffier believes that there is not in existence a single case of deep cancer of the mucosa which has been cured by radium. But he has seen very remarkable amelioration which indicates the employment of it when surgical removal is impossible. In such cases it is the best palliative which we have at our disposal at present. Schwartz thinks that radium relieves, prolongs, and renders operable tumors which were previously not so, but that it has never cured a deep tumor. Ricard thinks that radium should be considered a precious resource in inoperable cases. Morestin thinks that radium therapy can only be a palliative medication, or an adjuvant treatment complementary to surgical operation. Walther asks us to observe that sometimes the application of radium, while bringing about a rapid cicatrization and an apparent cure of the tumor, brings about a deep proliferation of the epithelioma. Routier also thinks that in some cases the application of radium may be more harmful than helpful.

Potherat and Tuffier showed remarkable results from instantaneous radiography. These instantaneous radiographs are obtained by the reinforced tubes the first of which made its appearance in 1896. Nogier, in April, 1910, made use of a German tube with which he obtained images in a tenth to a thirtieth of a second. Chatenet presented a new English tube of Watson, which is only a modification of the previous ones. Each of these has a secret method of manufacture. The reinforced tubes have, then, been employed for a long time. The novelty is the systematic use of the old and new intensified tubes with intensive installation, which allows us to transform rapid radiography into instantaneous radiography.

The characteristics which differentiate pyelonephritis of pregnancy from mild infections of the kidney and its pelvis rest on their evolution and their treatment, which explains sufficiently the condition of the patient in these cases. This is an infection of a serious nature against which a conservative therapeusis is the method of choice. Aside from the old medical means, catheterism of the ureters, and the reclining position of the patient, there are several methods which have been proved and which are harmless in any case. A new method has been presented by Tuffier and Mauté, vaccinotherapy. As the microbian infection is monobacillary, the preparation of a vaccine from microbes taken from the same patient to be treated has entered definitely into practice as a therapeutic method. The vaccine is prepared by making use of a culture on gelatine for twenty-four hours, which has been isolated from the urine. The vaccine is a sterilized emulsion of the twenty-four hour culture in a certain quantity of physiological solution; sterlization is obtained by addition of a small quantity of phenic acid. It is useful to know the dose injected, and for this reason the authors proceed to dosage by weight. The result of these injections on an acute pyelonephritis of pregnancy was remarkable after three injections; the pulse and temperature were reduced, the patient felt a sense of well-being, most remarkable, which continued definitely not only during the whole course of the pregnancy, but also after labor, which occurred without any difficulty. A month after labor the mother and child were in perfect condition.

OUR LETTER FROM THE PHILIPPINES.

OBSTETRICAL PRACTICE IN THE PHILIPPINES—PROPOSAL TO IMPROVE THE STANDING OF MIDWIVES—POPULATION OF MANILA—CHOLERA—PHILIPPINE MEDICAL SCHOOL—PHILIPPINE GENERAL HOSPITAL.

MANILA, June 15, 1910.

THE regular meeting of the Manila Medical Society was held at the Philippine Medical School at 8:30 p. m., June 6, 1910. A symposium upon obstetrics was had and many of the obstetricians of the City of Manila took part.

In the Philippines it has not been customary for male physicians to attend women during confinement, this duty generally being left to a poorly instructed class of midwives; as a result many unnecessary deaths are caused and much permanent harm is done. The question of improving this state of affairs has been frequently agitated. Recently a determined effort was made by the medical officers of the Philippine Medical School and of the Bureau of Health to make proper medical service available. With this end in view an out-patient obstetrical department was established to which were attached two nurses and a sufficient number of physicians so that one or more would be subject to call at all times. Patients are visited in their homes before labor and confined there if they do not wish to enter the hospital. During the early part of April only a few scattering calls were received, but these increased rapidly so that the daily average during May was 37 or a total of 1147 for the month.

The ignorant midwives are permitted to practice their calling without restriction. To remedy this the following resolution was proposed by Dr. Calderon: "The Manila Medical Society requests from the Honorable Governor General the appointment of a Committee in the City of Manila, which, in connection with the Bureau of Health, the Department of Obstetrics and Infants of the Philippine Medical School, and the 'Gota de Leche' Society, shall suggest whatever measures are found advisable for the reduction of the high infant mortality and the disappearance of intruders among the labor cases of the city." This was modified by the Manila Medical Society appointing a Committee, and when sufficient data have been collected the Society will consider the advisability of presentthe matter to the legislature.

During the month of January a new census of the City of Manila was made by the Bureau of Health and these figures have recently become available. They show that the number of inhabitants increased from 223,542, when the last census was made in 1907, to 234,400. The total number of Americans living in Manila is 4174; Filipinos 211,859; Spaniards 2364; other Europeans 644; Chinese 14,003; all others 1275. It is of interest to note that all nationalities, with the exception of the Filipinos, show a decrease. The Americans decreased by 1025 or approximately 25 per cent.; Spaniards by 530 or approximately 15 per cent. Europeans by 333 or 30 per cent. Chinese by 3935 or approximately 15 per cent.

During the latter part of April cholera was carried from Macabebe, Pampanga, to Bayambang, Pangasinan Province. Owing to the apathy of the local officials, the introduction of the disease into Pangasinan was not discovered until several days afterwards and only after five or six towns were infected. The Insular Bureau of Health immediately took charge and sent a large force of sanitary inspectors to the province but the disease had already gained such headway that a number of additional towns became infected and a total of over 300 cases occurred during the month of May. The second week in June an increase in the number of cases took place owing to infected food having been consumed at a large wedding festivity. As the participants came from many different towns and later returned to their homes this served still further to spread the infection. The disease is believed originally to have been carried from Macabebe to Bayambang on account of the transference from Macabebe to Bayam-

bang of a company of United States Army scout soldiers and the actual conveyance of the disease was in all probability due to the forwarding of food supplies from Macabebe and the travel caused by the wives and other camp followers of the soldiers. Since then the cholera has spread to Tarlac Province and cases have been found in Manila and Pasig which were directly traceable to Pangasinan and Bulacan Provinces.

The Philippine Medical School began its fourth annual session June 13, with 22 students in the Freshman class. Owing to a recent decision of the Holy See by which the San José estate was transferred from the Dominican Order to the Jesuit Order, the income of the Santo Tomas University Medical School has been practically taken away. This institution has been in existence over a hundred years and has graduated thousands of doctors during this time. Only recently large laboratory buildings were constructed and equipped and other steps taken to change the school to a modern institution.

The recent Philippine Legislature appropriated $20,000.00 for the construction of a dangerous communicable disease pavilion at San Lazaro and $25,000.00 for continuing the construction of the Culion Leper Colony.

The new Philippine General Hospital has been definitely placed under the Bureau of Health and upon its opening about October next will be made a division of that Bureau. The present Civil Hospital which is used almost exclusively for Government employees will be discontinued and the services rendered by it will be merged with the Philippine General Hospital.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 21, 1910.

Experimental Production of Actinomycosis in Guinea Pigs Inoculated with the Contents of Carious Teeth.—Frederick T. Lord has been led—by the finding of organisms resembling actinomyces in the sputum, by the lack of convincing evidence that actinomycosis is a contagious disease which suggests that the infection arises from within the individual, by the prevailing location of the disease about the neck or jaw, and by the fact that two patients recently seen gave a history of having had much trouble with the teeth—to turn his attention to the teeth as a cause of this affection. His investigations of the contents of carious teeth show that the number of organisms having the morphology and staining reaction of actinomyces, both in the smear preparations from the cavities of eleven cases and in the sections from the cavities of five cases, is variable. In some preparations they are present in great numbers and far outnumber other bacteria. This suggests that actinomyces plays an important part in dental caries. The intraperitoneal inoculation of guinea pigs with the contents of carious teeth was followed by omental tumors histologically identical with actinomycotic tissue and containing typical club bearing actinomyces granules in three of five animals. The constancy with which organisms having the morphology and staining reaction of actinomyces are present in carious teeth suggests that under certain conditions certain persons with carious teeth are liable to develop actinomycosis. In explanation of the infrequency of this condition compared with the numberless chances for infection it is suggested that invasion of the tissues by actinomyces does not always give rise to actinomycosis. It is probably that only in a small number of cases in which implantation of the organism occurs does it actually take root and lead to progressive lesions.

Suture of the Faucial Pillars for Hemorrhage Following Tonsillectomy.—R. H. Gilpatrick considers this the most efficient means of controlling bleeding but one so radical as to be advisable only in cases of continuance of hemorrhage after the application of the usual means of control. With the patient in the Rose position, the jaws open to the fullest extent and the tongue depressor introduced so that its tip presses against the base of the tongue at the lowest point of the faucial pillars and away from the side to be operated upon, a small round-pointed, fishhook-shaped needle, threaded with about eighteen inches of black silk or linen thread, is carried behind the lowest portion of the posterior pillar and is introduced forward through both pillars, taking enough tissue to insure its not tearing out. The head and tail of the suture are twisted together and secured by a shot slipped over them and crushed close to the point of suture of the pillars. The tail is secured between two convenient teeth. The suture is continued as a running, over and over, to the other end of the pillars, the bites being about one-quarter of an inch apart. The head and tail of the suture are again twisted together and secured by a shot and the long ends attached to teeth to prevent the shot falling into the larynx in case the suture tears out.

New York Medical Journal, July 22, 1910.

The Clinical Value of the Serodiagnostic Methods in the Diagnosis of Syphilis.—William Litterer gives the consensus of opinion concerning the latest interpretations of the Wassermann reaction from which he draws the tol lowing conclusions. (1) In internal medicine, neurology, pediatrics, surgery, in fact in every department of medicine, the Wassermann test is of inestimable value as corroborating or dispelling the suspicion of an active specific disease. (2) Under our present interpretation, a positive reaction means that an active syphilis exists and that it indicates that there should be an exhibition of antisyphilitic treatment. (3) Since antisyphilitic treatment invariably causes the disappearance of the Wassermann reaction, it may be an index as to the efficiency of a line of treatment in that particular case. (4) There are some nonluetic blood sera which cause a fixation of the complement. These sera are so rarely met with, and then not infrequently in such extensive pathological processes, that they do not vitiate the clinical value of the reaction.

Vaccine Therapy in Tuberculosis.—Herbert Maxon King discusses this subject from the standpoint of sanatorium treatment. At the Loomis sanatorium two classes of patients are advised to take up the tuberculin treatment: (1) Incipient cases which have been under observation long enough to justify the belief that they are not progressive and are without fever or other evidences of a marked general toxemia, and (2) that class of more advanced cases presenting evidences of arrested activity, but who still have cough and a bacillary sputum. The one demonstrable and constant result of the suitable use of tuberculin is tuberculin immunity. He feels that it gives the patient additional protection against his disease both in the form of present resistance and against future tendency to relapse. That general improvement and increased resistance follows its use in suitable cases is more and more felt by those who employ this agent therapeutically. They have been using bacillus emulsion and sometimes *bouillon filtré*, beginning with 0.00000001 gram (solid substance) bacillus emulsion and 0.0000001 cc. *bouillon filtré*, and proceeding by 50 per cent. increases until 0.0001 gram, or 0.00001 in the case of bacillus emulsion and somewhat larger doses in the case of *bouillon filtré* are reached; afterwards proceeding at the rate of 20 per cent. increases until the maximum dose is reached. They rarely if ever exceed a maximum of 0.001 gram bacillus emulsion, and 0.1 to 0.5 c.c. *bouillon filtré*. Individualization in treatment is quite as important as in other fields of therapeutics. They enjoined comparative rest on the day of the injection and strict rest for thirty-six hours afterward. There can be little doubt but that general reactions are undesirable. Tuberculin is contraindicated in laryngeal lesions where old fibroid infiltration has appreciably narrowed the glottis. In considering the treatment of secondary pyogenic infection by the specific bacterial product indicated by the character of the secondary infection the author says that they usually select cavity cases with persistent high fever, which does not yield to complete rest in bed, and have limited the cases to hospital patients where constant observation and control are possible. He describes the procedure by which it is determined as far as possible which organism is chiefly responsible for the symptoms and believes that the opsonic index determinations are of great value. An emulsion is then made from a growth of this organism, which is sterilized and standardized and given in initial dose of twenty to forty million, and which, if no contraindications arise, is increased at the rate of 100 per cent. until one hundred to two hundred million are given at intervals of from two to ten days. They have observed no untoward effects from such treatment and have never found that subsequent temperatures are any higher following an injection. In the majority of cases a relation can be traced between the treatment and the remission of symptoms, chiefly in lowered temperature. Their experience has been too limited to permit of very positive statements, but the plan seems reasonable and results seem to justify effort in this direction.

The Lacrymal Duct as a Portal of Infection in Blennorrhea Neonatorum and Its Prevention.—William Linton Philips shows that the minimum proportion of infected fetal eyes is caused by direct germ contact, and the maximum amount of infection travels indirectly by way of the nose, a cavity that remains open and would naturally become filled at the time of the rotary motion

of the head through the pelvis, with septic material, which is drawn further back by the first breath filling all nasal openings. Infection may travel from the nose to the eye in three ways, by the blood and lymphatics, by way of the antrum and frontal sinus, and by the lacrymal gland which is the more direct. The author recommends nasal cleansing and suggests disuccinic peroxide as a possible improvement over silver nitrate. Used in strength of from 1 to 500 to 1 to 30 there is no reason why it should not act better than other antiseptics because it penetrates the lacrymal canal and the conjunctival folds more deeply than those antiseptics which coagulate albumen. The mouth and the eyes should likewise receive care.

Journal of the American Medical Association, July 23, 1910.

Alcohol in Nephritis.—J. F. Hultgen gathered statistics from 150 patients in the Iowa State Inebriate Hospital and 311 cases in his private practice, making in all 461 cases, in which he found neuropathic and psychopathic lesions in 92.5 per cent.; marked and striking effects on the gastrointestinal tract in 82.7 per cent. There were no cardiovascular symptoms which might be termed characteristic of chronic alcholism unless it was the peculiar fetal qualities of the heart sounds. From these statistics it could not be proved that excessive drinking was in itself injurious to the lungs. Only 9.1 per cent. of the 461 showed evidences of nephritis, and only 5.24 per cent. showed temporary or permanent albuminuria, while 85.7 per cent. showed no evidence of deficient renal depurgation. From his observations the writer summarizes as follows: Alcohol when taken daily as it is by chronic inebriates is not an irritant to the kidneys. When nephritis occurs in a chronic alcoholic it is probably due to some other concomitant toxic agent, and not to alcohol. Alcohol when taken by chronic alcoholics, as a food or stimulant, is a diuretic. Those tissues which eliminate alcohol are least affected by it. This applies to the lungs but especially to the kidneys. Alcohol, while a toxicant, is also a detoxicant, ridding the body of various deleterious catabolic products. The comparative integrity of the kidneys in alcoholics may be due to the fact that the renal cells contain very few lipoids and lecithins and that therefore they are not at all acted upon by the narcotic molecule.

The Relation of the Blood-Vessel Wall to Coagulation of the Blood.—Bertram M. Bernheim observed, during the course of some recent surgery on the blood vessels, that clotting occurred on the adventitia with surprising rapidity, and it seemed possible that this might be accounted for by a substance contained in and secreted in the adventitia of the blood vessels, which on injury to the blood vessels was poured out and aided in the clotting process. He experimented with each of the three coats of the vessels separately and found that they all acted alike. It seems from these experiments that just as in the liver, muscle, etc., so in the blood-vessel wall itself there is a substance which, once the vessel is injured, probably aids in the formation of a clot. And if this is true, those engaged in the field of vascular surgery have still another problem to consider in connection with an already difficult and trying technique. The final solution of the problem, however, rests with pharmacologists and physiologists as in the case with many other problems of modern medicine.

Nervous and Mental Disturbances of the Male Climacteric.—Archibald Church, after reviewing the literature which seems to demonstrate that there exists a monthly rhythm in men, calls attention to the manifestations of the male climacteric. The author has been making observations upon which he bases his generalizations for the past ten years and finds that involutional insanity in men, as in women, is of tolerably frequent occurrence and presents no distinctions and practically no regular form of psychosis. In both sexes where insanity occurs there is almost invariably a well-defined tendency to mental instability. Aside from insanities he finds no considerable degree of elation, delirium, or maniacal manifestations, but almost invariably there are expressions showing an anxious tone of mental feeling. This varies from actual anxiety neurosis, with all the obsessions and phobias that mark the psychasthenic, to the rather simple anxieties of the neurasthenic and the hypochondriac. The mental features of worry and anxiety tend to fluctuate but there seems to be no monthly periodicity; the patients are apt to be more depressed during the early part of the day. Almost invariably there is a loss of weight and higher arterial tension than seems altogether attributable to their age or general physical condition. Gastrointestinal activities are reduced, and the patients are easily fatigued and show some general neurasthenia. Headaches, oppressed feelings in the chest, sudden sensations of an alarming nature, especially vertigos are generally mentioned. These conditions run a variable course of from eighteen months to three years, after which the patients regain a fair degree of their former mental and physical characteristics. In the management of these cases a reduction of the daily work is usually imperative. Vasodilators seem to be of value as well as general hygienic measures. A recognition of these climacteric features should enable the physician to maintain a more encouraging attitude toward this class of sufferers.

A Study in the Prevention of Adhesions.—J. R. Claypool, B. M. Vance, P. R. Roberts, and Cyrus W. Field have experimented upon dogs, comparing the value of olive oil and colorless liquid petrolatum in the prevention of adhesions. Every experiment has been controlled. In ten dogs treated with olive oil only one showed an adhesion, and in that case only along the line of incision between the peritoneum and the omentum. In six dogs treated with petrolatum all but one showed adhesions. In twelve dogs in which no oil was used adhesions were found in all but one. In a series in which adhesions were allowed to form, the wounds were opened and the adhesions broken down and oil introduced. In these the adhesions were not reformed. They conclude that olive oil seems to prevent the formation of adhesions in dogs and is worthy of a thorough trial in human surgery and that liquid petrolatum has but slight value for such a purpose.

British Medical Journal, July 16, 1910.

The Surgical Treatment of Varicose Veins.—M. Mamourian comments upon H. D. Sullivan's operation for the excision of varicose veins as described in the British Medical Journal of April 16, under the term "treatment by avulsion." He considers this plan unnecessarily elaborate, not sufficiently thorough, and somewhat unsafe, as it entails previous mapping out of the veins, the use of tourniquets, multiplicity of incisions, interference with the blood supply of the limb, profuse hemorrhage and contact of a foreign body with the blood with its attendant dangers. He objects to the term avulsion because the vein is not torn or pulled out, and thinks inversion or invagination should be more accurate terms. He recommends the following procedure: The prepared limb is elevated to empty the veins. A small, preferably transverse, incision is made high up in the thigh, over the saphenous opening, the long saphenous secured and divided between two forceps, and the proximal stump ligatured close to the femoral vein. Traction on the distal end of the vein makes it prominent all along its course. A small cut is now made on the inner aspect of the knee, the vein exposed and cut between two hemostats. A long probe, eye end up, is introduced through the lumen of the upper segment and pushed up until it comes out at the first incision. Next a ligature is passed through all the coats of the vessel, penetrating the vein twice and at the same time through the eye of the probe, and is tied firmly. By pulling on the distal extremity of the probe the vein is extracted in a few seconds, turned inside out. All the veins of the leg can be dealt with in similar fashion; if they are tortuous a gum elastic catheter of small caliber should be used instead of the probe. This method is not applicable to general or cirsoid varicosities.

Triplets: Mummified Male Twins and a Livnig Female Child.—George Aldridge reports the case of a primipara, aged 28, whom he first delivered quickly and easily of a mummified male fetus of about six months development. About an hour later he delivered the patient of a living female child of about eight and one-half months. About an hour and a half after this he delivered the woman of another male fetus of about four months' development. The placentæ were removed with difficulty. The two male fetuses were attached to one placenta, while the female child had a separate one.

Berliner klinische Wochenschrift, July 4, 1910.

Recognition of Syphilis and Its Activity by Provocative Injections of Mercury.—Glaser discusses the theory of Thalmann that endotoxins play a prominent part in the genesis of syphilitic lesions. In a recently published work by Wolff-Eisner on clinical immunity and serodiagnosis, the views of Thalmann are digested into formal propositions. From these it would appear that mercury destroys the spirochetes, at the same time liberating their endotoxins, the patient usually feeling and seeming worse during the earliest days of the treatment. But as a result of the operation of the endotoxins, antibodies are produced, with increasing immunity. As the undestroyed spirochetes slowly proliferate, the immunity becomes less. A delayed large macular roseola may now appear. The same mechanism is present in all relapses. The number of spirochete

foci in the body tends to diminish, so that relapses become more and more localized. In the tertiary stage the number of parasites is small, but very small quantities of endotoxins now suffice to produce lesions of an ulcerative character. When syphilis pursues a malignant course, it means that for some reason antibodies are not produced. The so-called metasyphilitic affections result from weakening of the tissues as a consequence of any severe lesion (alcoholism, infectious diseases, overexertion, etc.). The statement possessing the chief interest in this connection, is that mercury, through liberating endotoxins, causes temporary aggravation of the symptoms. This clinical observation goes back at least to 1869, when Stoehr described the fever which may follow mercurial injections. Knowledge as to this febrile reaction, however, seems to have remained latent until 1907, when Lindenheim placed the observation on record, that in early syphilis the initial injection of mercury produced temperature rise. Herxheimer had already noted that patients became worse after the first injection (so-called Herxheimer reaction). The author tested the subject of the provocative mercurial injection on latent syphilis—in the complete understanding of this term. The application of Thalmann's theory is Wassermann's reaction involves the possibility that with spirochetes present, mercurial injections must liberate the endotoxins. The febrile reaction which follows may be found in any case of latent syphilis which has given a positive Wassermann reaction. As the provocative injections have been tested with conflicting results, the technique of thermometry, etc., must be carefully elaborated, and the material selected with due care. The author's cases fall under two groups, as follows: (a) Individuals with gonorrhea, alcoholism, etc., with no history of syphilis, but positive Wassermann reaction, and fever following mercurial injection. (b) Individuals with history of syphilis, variability as to positive Wassermann, but with fever following the provocative reaction. It was learned that the very first injection did not necessarily cause fever, although subsequent ones might give rise to high tempertaures. The reaction must bear some relationship to anaphylaxis, but this must be revealed by future study. If subjects with positive Wassermann also react to mercurial injections to the extent of fever lasting from one to three days, we may conclude that the patient harbors virulent spirochetes and needs active antisyphilitic treatment.

Lesions Due to Massive Subentaneous Injections of Saline Solution.—Widerõe has sought to test this possibility on rabbits. Sufficiently large injections will after a time destroy the animals. In comparison, a man weighing 65 kilos. (143 lbs.) should receive daily in this manner about 5 liters of solution in order to produce a fatal result. The heart suffers chiefly, and is found dilated and relaxed, with subendocardial and muscular hemorrhages. Other organs showed capillary hyperemia and parenchymatous degeneration.

Relations of the Diastase in Human Blood to Diabetes.—Wynhausen, after mentioning the relative antiquity of this problem, gives his own experience and concludes that the variability of blood diastase in diabetes is very great, and that a comparison of diabetic with non-diabetic patients furnishes no diagnostic standard in regard to the severity of a case or from any other point of view. As far as we have gone, no quantitative relationship whatever has been detected between the sugar content of the urine and the amount of diastase in the blood. The same negative finding holds good for the relationship of the blood diastase to other diseases, such as nephritis and cachexia from any cause. It is not denied that in a few individuals a striking agreement between the two quantities may be present—thus in a case of diabetic coma, with high sugar content in the urine, there was a very low value for the blood diastase. The few positive cases, however, are outweighed by the negative and inconclusive results.

Deutsche medizinische Wochenschrift, July 7, 1910.

Rabies in Germany.—Lentz states that the disease is rare in Germany, and occurs chiefly in the dog. Many years ago it prevailed extensively in certain cities. To-day it occurs chiefly in localities which are continuous geographically with neighboring countries (Russia, Bohemia). From 1886 to 1901 about ten deaths annually was the mortality for mankind. These 150 fatalities in the human species are to be contrasted with nearly 10,000 deaths among dogs, and 1,664 in beeves. The mortality among certain other animals —sheep, pigs, horses—corresponds roughly to that in mankind. Cats show a smaller death-rate, while goats yield the smallest of all. About one goat per annum dies from this cause. Figures subsequent to 1901 bear out these death rates. The two Prussian institutions which supply prophylactic injections for bitten persons are located, respectively, in Berlin and Breslau, the former dating from 1898, the latter from 1906. The preventive injections have been absolutely harmless, and results obtained in animals themselves in which the disease is common furnish the best testimonial of success. For while bitten animals which are not inoculated show a morbidity and corresponding mortality of from 10 per cent. to 15 per cent., the death rate among inoculated animals is only about 1 per cent. Corresponding figures for mankind show that 235 human beings should have been rescued from this form of death since 1898. About 91 per cent. of human beings who have been bitten have been inoculated. The total deaths among this 91 per cent. and remaining (uninoculated) 9 per cent. are almost the same, and this furnishes a good idea of the value of preventive inoculation.

Secondary Saprophytic Infection with Tubercle Bacilli.—Hart relates a case in great detail which is designed to show that the deposition of tubercle bacilli in a given locality depends on a biochemical sensitiveness of the tissues. The bacilli may lead a saprophytic existence for a long period, causing no lesions, but poisoning the organism with their toxins, and producing supersensitiveness to injections of tuberculin. The author's case was one of primary bronchial cancer, with resulting stagnation of secretion in the compressed bronchioles. In this stagnant secretion tubercle bacilli settled, leading a saprophytic existence. During life the ophthalmic and cutaneous tuberculin relations had both been weakly positive, so that the diagnosis had been pulmonary tuberculosis. As already intimated, the lesions were purely cancerous; neither old nor new tubercles were present.

Appendicitis as Studied by Radiography.—Liertz concludes from a radiographic study of the appendix that the principal causal element is mechanical, chiefly anomalies of position. Bacterial infection is the second necessary factor. The anomalies of position favor stagnation, which comes about largely from fecal impaction in the cecum. Mere entrance of fecal matter into the appendix is not sufficient to cause the disease, for such entrance is much more common in the newly born and nurslings than in adults; while the incidence of appendicitis is reversed at these two periods of life. An anomalous location of the appendix therefore becomes a menace in later life.

How to Diminish Appendicitis Mortality by Preventing Abscess Formation and Peritonitis.—Kümmell concludes an important serial article with a number of weighty generalizations. Appendicitis is so common an affection that only one individual in five escapes it in some form or degree (judging from miscellaneous autopsies). It is an infectious disease, due to the greatest variety of bacteria, which attack an organ already diseased, although free from symptoms. Hardly a symptom is to be depended on absolutely in diagnosis; hardly a prognostic is to be trusted. The more recent alleged diagnostic resources, such as the leucocyte count, the determination of the viscosity of the blood, the Arneth blood picture, etc., add nothing to our resources. The author would remove any appendix, once it has become acutely inflamed; for in so doing one does away with the subsequent possibility of death from abscess and peritonitis. The early operation in acute cases (within the first 48 hours) gives a mortality of but 0.6 per cent. Nevertheless not all appendicitis cases require operation. If symptoms vanish within 12 or at most 24 hours, intervention may be unnecessary. These mild cases make up the bulk of all cases, and certainly require no early intervention. The author never saw a fatal ending in a very large number of these cases which received only medical treatment. Nevertheless, recurrence is the rule. "Physicians treat, surgeons cure," appendicitis.

The Role of the Thymus in Certain Pathological Conditions.—M. Lucien and J. Parisot say that many mishaps are laid to the hypertrophy of the thymus because we have not a sufficient knowledge of the normal size of the organ at any given age. They believe that, instead of taking on atrophy at a very early age, it continues large up to puberty. If death occurs and a large thymus is found it is laid to the gland, whereas it was, probably, of the natural size for the age of the child. In the second or third year it weighs 25 to 28 grams, whereas it has been thought to weigh, normally, 15 or 20 grams. It continues to grow for some years after this, up to puberty, and then gradually diminishes in size. Removal of the thymus in young animals causes lessened growth of the long bones. Ablation of the thymus in young children may be followed by serious symptoms, hence its total removal is contraindicated.—*Gazette des Hôpitaux.*

Book Reviews.

A Practical Study of Malaria. By William H. Deaderick, M.D., Member of the Arkansas Medical Society, American Medical Association, and American Society of Tropical Medicine; Fellow of the London Society of Tropical Medicine and Hygiene; Corresponding Member Société de Pathologie Exotique (Paris); President of the Tri-State Medical Society. Fully illustrated. Philadelphia and London: W. B. Saunders Company, 1909.

This is an excellent monograph on Malaria, and one that is calculated to be of considerable service to every medical practitioner. It is the work of one who has had an unusually large and successful experience with this disease, and is thus distinguished from similar volumes written by laboratory men. At the same time, the author not only refers to other authorities, but quotes, often at great length, from their writings; so that the volume really contains all that is worth while on Malaria. It combines with rare skill the results of scientific investigation with the practical observation and experience of the best type of practitioner. Special attention is paid to hemoglobinuric fever, and to the diagnosis and treatment of malaria. The etiology and rôle of the mosquito are fully considered; the subject of blood examination is dwelt on at length, and the author does not ignore the difficulties often attending this process; treatment is very fully discussed, and the efficiency of the various preparations of quinine is compared. Among the illustrations we are pleased to see portraits of Laveran and Ross; others worthy of special notice are those dealing with the mosquito and with blood examinations.

Year Book of the United States Department of Agriculture—1909. Washington: Government Printing Office, 1910.

This is the Sixteenth Year Book of the Department of Agriculture. It does not differ in character from the preceding ones, except that it is considerably shorter than that for the previous year, the decrease being made largely for reasons of convenience in forwarding and handling. The volume contains 36 text figures and 36 full-page plates, 11 of which are colored, and comprises numerous special papers of interest to farmers primarily. The usual statistical tables of crop and animal products are included at the back of the volume, together with a large index. The book is distributed free by Senators, Representatives and Delegates to Congress.

Die Krankheiten der Nase und des Nasenrachens. Mit besonderer Berücksichtigung der rhinologischen Propädeutic. Von Carl Zarnico in Hamburg. Dritte, neu bearbeitete Auflage, mit 166 Abbildungen und 5 Tafeln. Berlin: Verlag von S. Karger, 1910.

This is the third edition of this well-known treatise, incorporating in one volume what has heretofore been published in two. It follows along conventional lines, but is thoroughly up to date in its statements, and presents a most excellent arrangement of topics. It is undoubtedly one of the best works of its kind in the German language, and its translation into English would enable it to reach a much wider circle of readers of which it is well worthy.

Traité International de Psychologie Pathologique. Directeur: Dr. A. Marie (de Villejuif). Comité de Rédaction. MM. les Professeurs Bechterew (de St. Pétersbourg), Clouston (de Edinbourg), Grasset (de Montpellier), Lugaro (de Modène), Magnan (de Paris), Pilcz (de Vienne), Raymond (de Paris), Ziehen (de Berlin). Tome Premier, Psychopathologie Générale. Paris: Félix Alcan, 1910.

This is the first of three volumes, all of which are to appear within a year. It contains 1028 pages. The second volume will be devoted to clinical psychiatry and the third to therapeutics, in all that that word implies. The present volume is divided into ten chapters. Representative men from most of the European countries are collaborators. Among them we do not find the names of Kraepelin, Freud, Jung or any of the German school, except Ziehen. Naturally, Frenchmen predominate. Besides those mentioned in the title, we note the names of Deny of the Salpetrière and Roubinowitsch of the Bicêtre, Burlureau, Helme, Pietkiewicz and Sollier of Paris, Colin, Cullière, Dubief, de Fleury, Legrain, Lhermitte, Loiseau, Morel, Pactet, Picqué, Régis, and Sérieux of other parts of France, Bajenoff, Poussep, and Sikorsky of Russia, Winternitz of Vienna, Van Deventer of Amsterdam, Tamburini of Rome, Pick of Prague, and Moravesik of Buda-Pesth. Many of these names are well known to us, and will doubtless attract American alienists and neurologists to the work, which is intended, of course, primarily for specialists and as a work of reference. Three of the ten chapters of the first volume, the one before us, are prepared by Dr. A. Marie. These are entitled, respectively, an Essay on Psychiatric Anthropology, Chemistry of the Cerebral Substance, and Physiopathological Examination by Functions. These give one in themselves an idea of the scope of the work. Other chapters are on the Relationship between Psychiatry and Neurology (by Grasset), Neuropsychiatric Electrodiagnosis and Radiodiagnosis, General Pathological Anatomy in Mental Medicine, Psychological Evolution at Puberty, and Clinical, Psychological, Medico-Pedagogic, and Medico-Legal Methods of Examination. The work, though entitled an international treatise, is profoundly tinged with the teachings of the French school. These are somewhat at variance with the German ones at present gradually prevailing in this country. It will, however, be found extremely interesting and a valuable addition to the specialist's library. It is filled with illustrative cases, tables and illustrations, and describes in detail the principal hypotheses current at the present time concerning mental diseases.

Traitement Manuel dans les Maladies de la Nutrition; les Névralgies. Par le Dr. F. Wetterwold, Secrétaire Général de la Société de Kinésithérapie. Chargé de Mission en Allemagne par le Ministère de l'Instruction Publique (1909). Preface du Dr. H. Stapfer. Paris: Vigot Frères, 1910.

Any helpful suggestions relating to the rational treatment of painful affections are invariably welcomed by the profession. The day is happily past when we are content with the use of analgesics in the neuralgias. The general health is looked after; systemic poisons are eliminated; sources of peripheral nerve irritation are sought for and removed; yet sometimes surgery even is required as a last resort. In the little book before us the author states that he believes that in all neuralgic, neuritic, and arthritic affections attended by pain, there is present an interstitial neuritis analogous to cellulitis, panniculitis or edema of cellular tissue, whose origin is a disorder of nutrition. The seat of the neuralgia in these cases is in the microscopic ramifications of the nerves of the skin or of the subcutaneous or submucous tissue. The chief remedy is manual treatment, with special reference to nerve points.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited By Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Assisted by Leighton F. Appleton, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. June 1, 1910. Philadelphia and New York: Lea & Febiger.

The present instalment is on the usual plan of the June number, and contains articles on: Hernia, by W. B. Coley; Surgery of the Abdomen, Exclusive of Hernia, by E. M. Foote; Gynecology, by J. G. Clark; Diseases of the Blood, Diathetic and Metabolic Diseases, Diseases of the Thyroid Gland, Nutrition and the Lymphatic System, by A. Stengel, and Ophthalmology, by E. Jackson. We would again draw attention to Dr. Clark's contribution, which contains a masterly résumé on Cancer of the Uterus. Dr. Stengel's article is longer than usual, for which we are thankful. The part devoted to Diseases of Nutrition is timely and important.

Rhinology: A Textbook of Diseases of the Nose and Nasal Accessory Sinuses. By Patrick Watson Williams, M.D.; Lecturer on Diseases of the Nose and Throat at the University of Bristol, etc. Fifth Edition. London: Longmans, Green & Co., 1910.

The four previous editions of Dr. Williams' textbook have included Laryngology as well as Rhinology. He has now chosen to make two volumes instead of one, and the present is the first of the series. This portion of the enlarged work has been thoroughly brought ly to date in every department. The number of plates is unusually large, and they are arranged on the stereoscopic plan, every one displaying important points in the study of the nose and leaving more accurate and vivid impressions on the memory than can be achieved by any other means. The book is well printed on excellent paper. The author has the happy faculty of being able to distinguish the essentials from the non-essentials, and has compressed a large amount of information into a reasonable space. Naturally the general topic of sinus diseases is very fully treated, and there are interesting sections on the various ocular and other complications of this class of affections. The Appendix contains a well-balanced formulary, and there is a valuable paragraph on the proper method of making post-mortem examinations of these sinus cavities.

Emergencies of General Practice. By Percy Sargent, M.B., B.C. (Cantab.), F.R.C.S. Surgeon to Out-Patients St. Thomas' Hospital; Surgeon to the National Hospital for the Paralyzed and Epileptic, Queen's Square; and Alfred E. Russel, M.D., B.S. (Lond)., F.R.C.P.; Physician to Out-Patients, St. Thomas' Hospital. Oxford Medical Publication. London: Henry Frowde, 1910.

The purpose of this book is to supply to the general practitioner a source of information as to what to do in a case of the various emergencies which may arise in the course of the day's work. The authors do not claim that the work is intended to cover all the possible modes of treatment for every possible medical or surgical hurry call. On the contrary, in most cases but one line of treatment is given in each instance, that being the one which the authors have found to be the most useful and at the same time most easily carried out with the aids which are apt to be at hand. Opening with a discussion of the best anesthetic to be used in emergency cases, the book contains chapters notably upon the usual surgical emergencies, as wounds, burns, hemorrhage, fractures and dislocations, foreign bodies, but also the medical condition of dyspnea, pulmonary and cardiac affection, acute abdominal diseases and injuries, infectious diseases, convulsions, unconsciousness, and poisoning. Separate chapters are devoted to acute affections of the eye and the ear. In short, the book covers systematically practically all the emergencies except obstetrical, which occur in an ordinary practice. The book lives up to the title in dealing with the emergency alone, and practically neglecting after treatment. The greater part of the work is given up to treatment, though in cases where the immediate diagnosis of the condition is of importance this is briefly discussed. The book is well written, is concise, to the point, and rather dogmatic in style, most useful attributes in a book which, when needed, is needed quickly. It does, however, not lose any of its literary style by being brief. Each article is a unit, giving just such information as is necessary in the various conditions treated, giving it clearly and forcefully, and not using an unnecessary word. For the busy practitioner the book will prove to be a most valued friend in time of need.

A Practical Treatise on Fractures and Dislocations. By Lewis A. Stimson, B.A., M.D., LL.D. (Yalen), Professor of Surgery in Cornell University Medical College, New York; Surgeon to the New York and Hudson Street Hospitals; Consulting Surgeon to Bellevue, St. Johns, and Christ Hospitals; Corresponding Member of the Société de Chirurgie of Paris. Sixth Edition, revised and enlarged, with 361 illustrations and 65 plates in monotint. New York and Philadelphia: Lea & Febiger, 1910.

This book has so long been accepted as a standard work upon the subject with which it deals, and is so well known to teachers, students, and surgeons alike, that an analysis of its contents is unnecessary. The present edition consists of over 850 pages of closely written information upon the subject at hand. The additions since the last edition include the results of further study of the injuries of the small bones of the carpus and tarsus which has been made possible by the advance in *x*-ray diagnosis. Sections have been added on fractures of the floor of the acetabulum and the internal epicondyle of the femur and on backward dislocation of the lower jaw. The book is well illustrated with semi-diagrammatic drawings and numerous photographs and *x*-ray plates. The entire work lives up to the standard set by previous editions, and that is sufficient recommendation in itself.

The Care of the Child. By Mrs. Burton Chance. Philadelphia: The Penn Publishing Company, 1909.

The market has been flooded lately with booklets by physicians and nurses, the purpose of which is to tell the young mother what she should do and what she should not do to her baby. Most of these are written in an arrogant didactic style, and consist of a series of shopworn rules which tend more to confuse than to illuminate the mother. The present book, however, differs from most of those which have appeared recently. In the first place it may be understood even by a mother who is not an expert in higher mathematics. Involved feeding tables are conspicuous by their absence. Most striking of all of the features of the present book is that it not only tells the mother what is the proper thing to do for the baby, but it gives simple and satisfactory reasons for each direction. The mother who reads this book, unless her intelligence is of a low grade indeed, will become an enthusiastic supporter of the modern methods of bringing up children, and will not throw the book away disgusted with "new-fangled notions." The present book is the best and most sensible which we have seen upon this much overworked subject, and can safely be recommended by the physician to the prospective mother.

Mind Health. The Mental Factor and Suggestion in Treatment, with Special Reference to Neurasthenia and other Common Nervous Disorders. By Edwin Ash, M.D. (Lond.), Bachelor of Surgery of the University of London; Member of the Royal College of Surgeons, England; Licentiate of the Royal College of Physicians, London; Pathologist to the London Temperance Hospital; Sometime House Physician and Demonstrator of Physiology at St. Mary's Hospital, W., New York: William Wood & Co. London: H. J. Glaisher, 1910.

Physicians now for the most part accept the fact that mental impressions exert a powerful influence in the production of various forms of ill health. Do we, however, also, all of us keenly realize the powerful influence of the mind in the recovery of health? And do we utilize this factor to its fullest extent? Here is a little book, eminently practical, whose main object, as stated in the introduction, is "to show in what way we can directly bring Mind Force into play in the restoration of health, and to demonstrate the important part which should be assigned to suggestion in any reasonable system of mental treatment." The author does not consider hypnotism as necessary for success, and omits this form of treatment from the book. He first elucidates the *modus operandi* of mental impressions in the production of physical disorders; then notes the influence of surroundings and attendants, etc., and sets forth his principles and methods, and, finally, describes their practical utilization.

Prescription Writing and Formulary. By John M. Swan, M.D., Associate Professor of Clinical Medicine in the Medico-Chirurgical College of Philadelphia; Instructor in Clinical Pathology and Tropical Medicine, Philadelphia Polyclinic and College for Graduates in Medicine; Fellow of the College of Physicians of Philadelphia. Containing 1043 prescriptions. Philadelphia and London: W. B. Saunders Company, 1910.

This little volume is likely to prove very useful to medical students and recent graduates. The part dealing with prescription writing is ably and concisely presented; the Latin is much more accurate than is usually the case in books of this kind, and the United States Pharmacopeia is taken as the basis or storehouse of supplies for illustrations. This is as it should be in a book intended for students; for, while the experienced practitioner may draw his remedies from any source that seems suitable to him, the beginner will find enough (and more than enough) to learn in the preparations given in the U. S. P. The prescriptions given in the last part of the book seem to be well selected; and, while they are amply sufficient, they are not so numerous as to bewilder the seeker after therapeutic information.

Surgical After-Treatment. A Manual of the Conduct of Surgical Convalescence. By L. R. G. Crandon, A.M., M.D., Assistant in Surgery at Harvard Medical School; Assistant Visiting Surgeon to the Boston City Hospital; Consulting Surgeon, Frost General Hospital. With 265 Original Illustrations. Philadelphia and London: W. R. Saunders Company, 1910.

This volume is written for two classes of practitioners—house surgeons in hospitals and general practitioners in communities which are not surgical centers. For the latter class this work is particularly valuble, the more so as every procedure advised herein has stood the test of practical experience. The house surgeons, as a rule, have the traditions of their own particular hospital to guide them; but as a help in case of emergency or something new, this book will stand them in good stead. The first half of the work consists of thirty-nine chapters, and treats of everything that concerns the comfort and welfare of the patient in a general way. The latter part deals with the treatment necessary after special operations on the various parts of the body. There is a chapter of over 160 pages on Therapeutic Immunization and Vaccine Therapy, written by a disciple of Sir A. E. Wright. The book is well planned and clearly written, and many a practitioner will find it a most useful supplement to any volume on Surgery. It is a pity that the work runs to 800 pages, for its size may prevent many from possessing and reading it. With the utmost care it seems as if we were bound to take our Surgery in many volumes, as witness the various volumes on Surgical Anatomy, Surgical Diagnosis, Surgical Pathology, Surgery, Operative Surgery, and now Surgical After-Treatment.

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-sixth Annual Meeting, Held in Washington, D. C., May 2, 3, and 4, 1910.

MORTON PRINCE, M.D., OF BOSTON, PRESIDENT, IN THE CHAIR.

Monday, May 2—First Day.

President's Address.—Dr. MORTON PRINCE of Boston opened the meeting with an address entitled "Cerebral Localization from the Point of View of Function and Symptoms, with Special Reference to von Monakow's Theory of Diaschisis." Dr. PRINCE said he had chosen as a subject upon which to address the association that of the doctrine of cerebral localization from the point of view of function and symptoms. The doctrine of cerebral localization acquired a very different significance according as to whether it meant that the brain could be mapped out into a number of circumscribed areas in each of which could be located a definite psychophysiological faculty or function, or whether it meant only that these areas contained anatomical elements which were made use of for the physiological expression of function. The doctrine of cerebral localization resolved itself into the question whether the localization was of symptoms or of function or whether it was only an anatomical localization of fibers. It too often happened that the formulæ of localization did not work in diagnosis. It not rarely happened that clinical and pathological findings were contradictory. Thus, on the one hand, extensive lesions in one or other of the recognized cortical centers ran their course without symptoms, and, on the other hand, focal symptoms, pointing to disease of these centers, developed in cases in which no anatomical alterations were found at autopsy. There was a growing dissatisfaction with the currently accepted doctrine of cerebral localization; a feeling that it was in many respects inadequate. The first blow to the traditional localization of function in the cortex had been received when Marie launched his attack on the currently accepted doctrine of aphasia. Whatever the outcome of the reinvestigation of this question might prove to be, it was evident that the beautifully diagrammatic concepts of the function of language and of aphasic disturbances of this function had been relegated to the scrap heap of the phantasies of science. Our former naive conception of aphasia could never be revived. The fact, the author believed, it would be found to be that, whether the third left frontal convolution, the first and seond left temporal convolution or other areas took part in the function of language or not, the function as a whole, as a psychical process, was a widely distributed one in which were engaged many dynamic processes and anatomical "centers" and a lesion of any one of several "centers" might give rise to all modes of aphasic disturbance. The contest had centered largely around the question whether a lesion of Broca's convolution gave rise to the motor type of aphasia and, therefore, whether in this convolution could be localized so much of language as was lost in this type. In thus stating the problem there was plainly a confusion of concepts: the one was a clinico-anatomical question involving a particular syndrome; the other a question of localization of function. In distinguishing between these concepts perhaps the difficulties might disappear, for a lesion might theoretically give rise indirectly to a group of language symptoms without being the seat of language function. The clinicoanatomical data themselves were contradictory. As, for example, (1) lesions of the third frontal convolution did give rise to a clinical aphasic syndrome of the so-called motor type; (2) destruction of Broca's convolution might be accompanied by simple mutism—or pure motor aphasia of the so-called subcortical type; (3) it also appeared to be true that in a considerable proportion of cases of aphasia, characterized by loss of the power of word-formation and articulation, Broca's convolution had been found intact. In any theory of aphasia as a clinical syndrome and in any theory of function these discrepancies must be reconciled. Might it not be that a lesion in the third frontal convolution might occasion a disturbance of language of the so-called motor type and yet this convolution not be an essential factor in the functioning mechanism of language? If time had permitted, other syndromes and functions might have been taken for analysis, for example, astereognosis, asymbolia, apraxia, in which similar contradictions would be found. Von Monakow, whose clinical experience and pathological training entitled his views to great weight, had pointed out the inadequacy of the generally accepted doctrine of localization to account for these contradictory phenomena. He believed that there was some error in the form in which localization was conceived by most clinicians. To-day, as formerly, two sets of experiences stood opposed to one another, the negative and the positive, and invited anew discussion of the doctrine of localization which had been declared closed by many writers. We might ask how these contradictions can be explained. To answer this von Monakow had proposed a theory, of the greatest interest and challenging examination, which was known as *diaschisis,* and which had for its basis the results of experimental investigations. After removal of focal areas in the cortex certain symptoms were temporary, while others, which were purely local, were permanent. These latter, or residual, symptoms alone represented the function or part of function that was localizable in a given center. So-called focal symptoms were in large part a complicated reaction of unimpaired areas of the central nervous system to the local cortical lesions. By diaschisis was meant a functional shock-like inhibition of previously uninjured distant areas produced by the dynamic influences of a lesion anatomically connected with such areas. Through the break in the continuity of the conducting associative paths the eccentrically lying brain foci were robbed of their natural sources of stimulation and in part isolated. Only the directly injured elements gave rise to the permanent symptoms and secondary degenerations. So far as the theory definitely distinguished between the localization of symptoms and the localization of function, the author thought it might be safely insisted upon as the only interpretation that could reconcile the facts of clinical and pathological observation. The diaschisis theory was fruitful in other fields than that of cerebral localization. For example, its possible applications in the explanation of focal symptoms without focal lesions would occur to everyone.

A Report of Three Prefrontal Tumors.—Dr. F. X. DERCUM of Philadelphia read this paper, saying that his first and second cases had been inoperable; in the third the tumor had been removed, but was of enormous size, weighing 7¾ ounces. Death had occurred fourteen days after operation. The report of operation and subsequent surgical history would be given by Dr. John H. Gibbon. The symptoms presented in the above cases were of unusual interest. Vague mental symptoms had been present in all of them. Case I had suggested symptoms not unlike those of profound cerebral exhaustion or of a beginning paresis. Headache had never been a marked feature, and had been elicited only by questioning. It had existed only for a short time previous to death; vomiting had occurred but once, and that only toward the very close of the illness. There had been absence of optic neuritis and of any involvement of the visual fields. The only symptom which had been at all suggestive had been one attack of slight twitching of the left leg and possibly twitching of the left arm, which had occurred a few days

before he came under observation; the attack had been very brief in duration, and had not been attended by loss of consciousness. Occasionally psychic vesical incontinence had been present. In the second case there had been early headache, optic neuritis, and vomiting, all of the symptoms being typical and marked. The feature of special interest was the slight flattening of the lower half of the right side of the face and the equally slight involvement of the left leg and arm. These symptoms had been in all probability due in part at least to indire pressure. The subjective sensory disturbances in the left leg and left arm, namely, pain, and the hyperesthesia of the left arm and both legs were somewhat difficult to explain. The occurrence of typical areas of hysterical painful hyperesthesia under both breasts and over both groins was exceedingly interesting and important, and must be borne in mind in considering the other sensory symptoms present. The area of hyperesthesia upon the left parietal region had been also small, and resembled in other respects an area of hysterical hyperesthesia, though it had been present on the same side as the tumor; the question arose whether the left hemiparesis, present for a time only, had not been also hysterical in origin. In Case III optic neuritis had been pronounced. Headache had been scarcely, if at all, present. Vomiting had been absent. Case III was remarkable for the size of the growth, which had probably existed for a long time previous to the seizure, which occurred in the summer of 1908. That so large a growth could have been present and the patient still have been able, even in a degree, to attend to his business and ordinary affairs was very remarkable. Finally, the resemblance of the mental symptoms in Cases I and III to those of paresis was worthy of comment. Case I had been placid, indifferent, and had not manifested the least anxiety as to his condition. Case III had been at times distinctly expansive, good-humored, and not infrequently laughed and joked. Case II, though quiet, complained greatly at times of suffering; at no time had she been jocose, nor had there been any tendency to laughter or hilarity. Indifference to the sphincters had not been observed, and there had been no epileptiform seizures. Th eye muscle symptoms had made their appearance late, and were probably to be referred directly to the frontal lobe lesion; in part they might have been due to the blindness and the absence of fixation. In many respects the above cases conformed to the ordinary observations made in prefrontal tumors. This was particularly the case as regards the mental symptoms which had been most marked in Case III, less marked in Case I, and least in Case II. Psychic incontinence had been pronounced in Cases I and III. Epileptiform seizures had been present but once in Cases I and III and absent altogether in Case II. Optic neuritis had been present in Cases II and III and absent in Case I; the swelling had been more marked on the side of the tumor in Case II and slightly greater on the side opposite the tumor in Case III. Local tenderness of the skull had been present only in Case II, on the same side as the tumor, but parietal, and not frontal. Finally, it was interesting to note that in none of the cases was there present any ataxia. It should be added that no *x*-ray examination had been made in Case I. In Case II an *x*-ray examination had been negative. In Case III an *x*-ray examination had also been negative, save that it had reveald some irregularity of the inner surface of the frontal bone upon the right side; also some apparent thinning of the bone. The possible etiological value of trauma was well illustrated in Case I.

Dr. E. W. Taylor of Boston said that the two main points that Dr. Dercum had brought out were very interesting. In the first place, the mental condition; in the second place, the epileptiform seizures. From what Dr. Dercum had said, and Dr. Taylor presumed it would be generally accepted, there was no definite type of mental diseases to reveal frontal lobe lesion. He recalled distinctly a patient in which the mental symptoms, instead of being apathetic, were of precisely the opposite sort. The man had been a young Army officer, previously healthy. He had been extraordinarily apprehensive, he had developed all sorts of phobias, had been unable to go into crowded places, buildings, and so on, and had presented all the appearances of a mental state. He had had slight epileptiform convulsions, which Dr. Taylor misinterpreted as hysteroid convulsions. He had disappeared from view, and if he had not heard his subsequent history he would have regarded him as a psychasthenic patient. He had later come under treatment and died. There had been found an extensive prefrontal tumor, gliomatous in type, very difficult to distinguish from the brain itself. The points of importance had been incidence of slight seizures, epileptiform in character, and, secondly, and still more confusing, were the phenomena one so often sees in the neuroses of psychasthenic character.

Dr. Edward B. Angell of Rochester, N. Y., said he had been impressed with the lack of symptomatology of prefrontal tumors. We got many of these cases without headache, nausea, vomiting; without any of the motor symptoms, and without any of the hemiplegias or disturbances of one side of the body. A case had come under his observation one year ago, a very successful and intelligent business man. He had suddenly become apathetic. His family had first noticed this because he had received news of a disaster with unconcern. Aside from that condition he had had no symptoms whatever. He had had an attack of grippe and had had quite a nasal discharge and quite an increase in the white blood cells. Here had been a case where we would have had reasons for believing we had had acute trouble by extension from the nasal chambers. The mental symptoms had been such as to indicate much pressure. When he died it was shortly. He had a tumor as large as Dr. Dercum's patient in the left prefrontal lobe.

Dr. Hugh T. Patrick of Chicago inquired the state of the sense of smell in these cases.

Dr. Herman H. Hoppe of Cincinnati said he wished briefly to refer to one symptom-complex which had obscured the diagnosis in a case he had seen in which there had been absolutely no general symptoms of brain tumor. This tumor had grown from the sella turcica and involved both portions of the frontal lobes. The earliest manifestations had been in reference to the optic thalamus. This man had gone on with business after developing atrophy of the optic nerve, then he had begun to develop sluggishness of the pupils. In the subsequent history there had been a pure, simple dementia, so much so that the diagnosis of dementia paralytica had been made. The man had died in an insane hospital, and the autopsy had revealed the tumor.

Dr. George W. Jacoby of New York said he had had the pleasure and benefit of seeing the case Dr. Dercum had reported, and, after having seen that case had compared it with a couple of others he had previously seen. It seemed to hi mthat we could be very positive that there is no pathognomonic series of symptoms of prefrontal tumors. One way diagnosis could be made was by sequence of symptoms or symptoms dependent upon pressure; the occurrence of aphasia and involvement of the motor tract, the significance of reflexes, all of which were helpful and indicative of the associated pressure.

Dr. E. E. Southard of Boston said that he had found that in some cases it was profitable to examine histologically other parts of the brain than those directly involved in the tumor. He recalled a case of tumor of the prefrontal lobe in which epilepsy had not existed, but in which there had been a unilateral paralysis on the same side as the tumor,

and histological study of the precentral gyri had shown that for some reason on the opposite side there had been absence of cells.

Dr. B. Sachs of New York said that in regard to frontal tumors, he did not know why they were spoken of as prefrontal tumors. There were two points of vital importance in regard to the question of operability. First of all, the focal signs, as in many instances they gave no idea of the actual size of the tumor and the probable result of an operation. So much depended upon shock, the shock seemed to be in direct proportion to the size of the tumor, that one of the most essential points for determining the operability of a tumor was to try to decide whether the tumor was of large size or not, and whether the symptoms gave one any idea of the size of the tumor. The other points belonged to all tumors. A great deal depended upon the character of the tumor, particularly in the development of symptoms. It was a very different thing whether the brain substance was being invaded by tubercle or sarcoma, or whether it was being gradually invaded by a glioma, and some of the peculiarities in regard to tumor of the frontal lobe might be explained by the fact that many of these tumors had been slowly invading gliomata, whereas the cases in which the tumor had been much more destructive the symptoms were more marked. The destructiveness of the tumor was in direct relation to the distinctness of the symptoms. Dr. Sachs had observed a case which had presented during life absolutely nothing else but epileptiform seizures, suddenly die from hemorrhage from a tumor which on post-mortem examination had proved to be a huge glioma involving the entire one hemisphere of the brain. This was a point we often lost sight of, that is, the different character of the symptoms in relation to different structure of the tumor. Glioma seemed to cause fewer symptoms than any other tumor because the brain tissue accommodated itself much more readily to the slow invasion of the glioma.

Dr. D. D. Wolfstein of Cincinnati referred to a case in which he had made the diagnosis of tumor of the frontal lobe. It had been in the left frontal lobe, and of very large size, but there had been absolutely no mental disturbance. The only symptoms had been progressive optic atrophy, with complete loss of vision. There had been a suspicion of epileptiform seizure. Very often these tumors passed far back, and tangental fibers which passed through the capsule were involved. Those cases which simulate epileptiform seizures might in this way be explained.

Dr. Dercum, closing, said that in these cases the sense of smell had been preserved. In a case which he had reported to the association some years ago the sense of smell had been destroyed. He thought Dr. Southard's position well taken. It seemed to him that the epileptiform attacks in these cases were perhaps due to pressure about the base. He was in entire accord with what Dr. Sachs had said in reference to the size of the tumor. The first two cases had been round-celled sarcomata, the third had been endothelioma, and sprang from the dura of the base. As regards the term prefrontal, Dr. Dercum felt it was a justifiable term, provided we strictly meant that the tumor had advanced up in front of the motor tract itself.

Report of a Case of Resection of Dorsal Spinal Nerve Roots for Gastric Crises of Tabes.—Dr. John Jenks Thomas read a paper which was prepared jointly with Dr. Edward Hall Nichols, saying that gastric crises of tabes might be very severe, and have such effect upon the general condition as to lead to death. The attacks not infrequently constituted the earliest symptom of the disease. This fact had frequently led to error of diagnosis and the performance of useless operations. Post mortem, in fatal cases, the stomach usually showed no changes, even when blood had been vomited. The most probable theory as to causation was that the pathological basis consisted in changes in the sympathetic nerve. This view had been adopted by Förster, and led him to resect the dorsal thoracic nerve roots, by which the sympathetic nerves were connected with the central nervous system. Aside from the first case of resection of dorsal nerve roots for this symptom, reported by Förster and Küttner, one other case had been found in the literature, reported by Bruns and Sauerbach, both operations having been done in the summer of 1909, and both followed by complete relief. The patient, whose case was reported in this paper, was a man of 32 years, a widower, with one healthy child, a girl of 13. This child had been followed by three or four miscarriages of unknown cause. Syphilis was denied. The gastric crises had begun about eight years before, and in October, 1905, the abdomen had been opened at a hospital, but nothing abnormal found except a few adhesions of the omentum to the gall bladder, which did not pull upon the stomach. These adhesions had been freed. The attacks had continued, and he entered the Boston City Hospital August 3, 1908. At that time his attacks came at intervals of one week to one month, and lasted from one to ten days—with severe pain and vomiting, accompanied usually by diarrhea. There had been no loss of control of the bladder, but some diminution of sexual desire. No lancinating pains, no diplopia, and no ataxia in walking or standing, but very slight ataxia in movements of legs with eyes closed. Hypotonicity in legs well marked. Pupils moderate size, regular, and equal, reacting with accommodation, but not to light. Patellar and Achilles reflexes equal and present. At this time he had become habituated to the use of morphine, and was taking about a grain a day. The attacks continued, gradually becoming more frequent, seldom a week passing without one. In August, 1909, the Noguchi serum test for syphilis had been positive. At the time of operation the weight, formerly 145 pounds, had fallen to 100 pounds, sensation for touch and pain was diminished on the chest from the third to fifth rib, and the abdominal reflexes were lively, the left Achilles jerk had disappeared, though the right one and the patellar reflexes were present. March 3, 1910, the seventh, eighth, ninth, and tenth thoracic dorsal roots were cut. After the operation for a time there was severe twitching of the abdominal muscles at times and pain about the chest, which gradually diminished. He had vomited once, while still in the hospital, after being given mercury by mouth, and once after his discharge, after eating beans, but neither time had there been any pain, nor was the vomiting persistent, being over within an hour. There had been the same condition on examination, but an absolute loss of the sense of touch and pain from the level of the sixth rib to three fingers breadth above the umbilicus, and from this area no abdominal reflex could be obtained, but it was present, and increased on irritating the skin of the lower abdomen. The man regarded himself as cured of his crises, but had not gained in weight, and was attempting to diminish his morphine, and had reduced it to two quarter-grain doses a day.

Dr. John K. Mitchell of Philadelphia asked how Dr. Thomas justified the diagnosis of locomotor ataxia with knee jerks still present. In the last year he had seen one case of tabes in which gastroenterostomy had been done and two cass in which operation had been done for gastric crises, and two in which gallstones had been hunted for. Presumably in none of these cases had the surgeons taken the pains to examine either the knee jerks or the eye reflexes.

Dr. Philip Coombs Knapp of Boston said he must confess that theoretically he was somewhat skeptical about the results of operating upon the posterior roots for the gastric crises of tabes because of the physiological fact that the nerve supply of the stomach is dependent very

much more upon the vague than upon the sympathetic. The success of Dr. Thomas' case, however, had led him to have another case, which was very similar to his, operated upon by Dr. Blake a day or two ago. In answer to the objection Dr. Mitchell had raised to the diagnosis in Dr. Thomas' patient, he said that in the last few years, as well as previously, he had seen a good many cases with pretty clear tabetic symptoms but with retained ankle jerk.

Dr. Harvey Cushing of Baltimore said he was far from being in accord with Dr. Mitchell's statement that surgeons were a bad lot, especially in Baltimore. However, he would like to make an arrangement with Dr. Mitchell whereby he would turn over for Dr. Mitchell's collection the list of cases of the kind he mentioned of which Dr. Cushing had cognizance in return for the list of cases of brain tumor long treated for gastric headaches. Dr. Cushing did not think any surgical cases of disease reported after they had been done a month really conveyed a fair general impression as to what the author's results were.

Dr. Joseph Collins of New York said that in the discussion the association was liable to lose track of what they had started out for, that is, to determine the feasibility and advisability of this operation. He was very much in favor of the operation in cases that were intractable. Relative to Dr. Mitchell's question in reference to knee jerks being present in tabes, Dr. Collins said that in ten out of twenty cases of tabes the knee jerks and ankle jerks were present.

Dr. Thomas, closing, said that he was very sorry that Dr. Mitchell should have been disturbed by the patient's having knee jerks. He agreed fully with Dr. Collins in saying we frequently made the diagnosis of tabes in the presence of knee jerks and ankle jerks. The reflex of the pupils had been absent to light, although retained at first, and the man had had marked hypotonicity, which Dr. Thomas thought was fully as important to tabes as taxia, and he had felt justified in calling it one of tabes. Dr. Thomas tried the Noguchi test, and it had been positive for syphilis. The count of the cerebro-spinal fluid was not made. At operation there was a marked degeneration of the pia. Operation should be done only in the most severe and intractable cases, those where some danger to life existed.

Oculomotor Palsies Due to Vascular Constriction in Cases of Brain Tumor.—Dr. Harvey Cushing of Baltimore read this paper, saying that oculomotor, and particularly abducens palsies, more or less fluctuating in degree, often occurred in cases of tumor, and were included among false localizing signs. Various explanations had been offered for their occurrence. Contrary to the usual anatomical description, these nerves underlaid the lateral branches of the basilar artery, which had a rubber band effect, and so constricted the nerves as to block their transmission of impulses. The condition was most apt to accompany tumors of the posterior fossa.

Tuesday, May 3—Second Day.

A New Type of Pressure Myelitis.—Dr. Graeme M. Hammond of New York read the paper, saying that the description of this disease was based upon the study of seven cases which had come under the author's observation. The pathological conditions seemed to consist of the development of an enormous amount of new bone tissue, which spread over a number of vertebræ and adjacent rib ends, obliterating all articulations and giving the effected vertebra and ribs the appearance of being one single piece of bone. The development of new bone also occurred within the vertebral canal, and gave rise to compression of the cord, causing both sensory and motor symptoms, but eventually leading to the most intense rigidity of the entire voluntary muscular system below the level of the lesion. There had been the gradual development of the "Bible back" or forward curvature of the vertebral column seen in spondylose rhizomelique, but in none of the cases had there been any evidence of rheumatism.

Dr. B. Sachs of New York said that he had seen a number of cases that had offered some difficulties in diagnosis, particularly in trying to make the differential diagnosis between such conditions as described and a simple myelitis. Within the last few months he had had at Mt. Sinai Hospital, New York, two cases of absolute spinal rigidity. An *x*-ray picture had been taken in one case and showed a condition very much like the one presented by Dr. Hammond. In this case, a man of about 35, the rigidity of the spinal column had been absolute from the third or fourth cervical vertebra to the very end of the spine. In fact, in this case there had been no movement of the body possible except slight movement of the head forward and a slight lateral movement of both sides. There had been extreme contractures and atrophies. The man as he lay in bed had his knees so completely contractured that you could hardly put a hand between the posterior surface of the thigh and the posterior surface of the calf, the legs were locked together, and there was absolutely no motion of any part of the leg except of the toes. The atrophy was more extreme than he had ever seen it in any case of ordinary spinal origin. There was hardly a bit of tissue left; when you pressed the skin it seemed as if you had the bone in the hand. So far as the diagnosis was concerned, he was not ready to suppose this represents an entirely new type of disease, although he did not want to deprive Dr. Hammond of the honor if he could prove it. Dr. Sachs thought these cases were closely related to the *spondylose rhizomélique* type. He hoped that in all these cases of mysterious spinal disease an *x*-ray picture would be taken, for nothing was more serviceable in case of mysterious spinal disease in reaching a diagnosis when medical signs have been wanting.

Dr. D. J. McCarthy of Philadelphia said that his feeling was that we were dealing in these chronic cases of rigidity of the spine with not only a factor involving the bone and cartilages, but an involvement of the spinal dura on its external surface, and this should be examined very carefully microscopically. It is more rational to suppose that where you have an extensive process, it would more likely be due to inflammatory changes in the dura than a condition localized to one group of joints. The bone changes were secondary, and were not the primary disease.

Dr. William G. Spiller of Philadelphia said he had not quite understood from Dr. Hammond the distinction between the type he had described and that which von Bechterew described. Von Bechterew made a distinction between his forms and those of Marie. There were in this connection two other kinds of disease. They were not likely to cause confusion in diagnosis, but they were interesting to mention. Eight or ten years ago Dr. Mills and Dr. Spiller reported a case of a man who had been paralyzed and had had rigidity of the spinal column. They had found that the dura was firmly adherent to the bodies of the vertebræ throughout the whole course of the spinal canal, and in removing the cord it had to be cut away inch by inch. This could be recognized by the *x*-rays. In the past winter Dr. Spiller had had an interesting case in a man who developed paralysis and exaggerated reflexes of his lower limbs. The disease gradually progressed upwards, involving his left arm and then the other arm, and the course of the disease had been only a few weeks. He found a growth on the outside of the dura which under the microscope showed probably endothelioma. This was the first case he had seen of real endothelioma developing primarily between the dura and the bodies of the vertebræ.

Dr. Hammond, closing, said in regard to the case Dr.

Sachs spoke of, he thought there was no doubt that it was a case of spondylose rhizomelique; he had the muscle changes which go with such conditions. In none of Dr. Hammond's case had there been any anchylosis of the hip joints, or atrophy. The rigidity had been a muscular spasticity, just as we see in a myelitis of the crossed pyramidal tract, with the attendant symptoms of clonus, Babinski reflex, and exaggerated reflexes. This had persisted until rigidity had become great. All these cases died; not so the cases of spondylose rhizomélique; many of them lived on for years. He agreed with Dr. McCarthy that the bone changes were secondary. In all the cases the first symptom elicited had been the curvature and rigidity of the spine, coming on three or four years before the first spinal symptoms became apparent. In regard to the changes of the dura spoken of by Dr. Spiller, in the only case he had a chance to examine the dura showed no adhesions. So he doubted whether adhesions of the dura had anything to do with the symptomatology of this condition. It simply seemed to him that on account of the increase in the bony tissue the spinal cord was gradually compressed and destroyed, and these patients died. He did not think it tallied at all with any of the cases described by von Bechterew. It might not be a new disease, but it was new to Dr. Hammond, and he had no doubt that when attention was called to it we would find a good many cases of similar type, but it was not that of spondylose rhizomelique.

Cyst (Possibly Traumatic) of the Spinal Meninges Removed by Operation, with Recovery of the Patient. Remarks on the Location of the Centers for Testicular Sensibility.—Dr. Charles S. Potts of Philadelphia read this paper, saying that a farmer, aged 42 years, received a blow upon the back eighteen years before coming under observation. No serious symptoms had been caused at that time. Two years before admission to the German Hospital he had begun to have attacks of severe shooting pains in the left hypochondrium. During the attacks the lumbar muscles of the left side had been thrown into spasm. At this time a girdle pain extending through the umbilicus had also been present. A few months before admission first noticed difficulty in walking. Examination showed a very ataxic gait. Muscular power of the legs good. The Babinski reflex was present on the right side. The cremaster reflex was present on the left side, but absent on the right. Abdominal reflex absent. Station poor, heel to knee test poorly performed, unable to recognize the direction of passive movements of the toes. An area of possible hypaesthesia and hypolgesia extending about four inches below the right groin. Both testicles completely insensitive. Sphincters normal. The laminæ of the sixth, seventh, eighth, ninth, and tenth thoracic vertebræ had been removed. A soft growth, pronounced by the pathologist to be a traumatic cyst, had been found, extending subdurally from the lower angle of the wound (first lumbar segment) upwards for about three inches. Complete disappearance of pain. Testicular sensibility returned and there had been nearly complete disappearance of all the other symptoms.

Dr. Sanger Brown of Chicago said he was struck in reading over the abstract of Dr. Potts' paper with the fact that the author had spoken of centers for sensibility in the spinal cord. Now if one spoke of a center of sensibility Dr. Brown thought he usually had in mind a group of bodies of neurons which presided over a particular function. This was well understood to apply properly to motor neurons. We have pretty well-defined and pretty well-demonstrated centers for motion, but we might safely say that in this sense there were no sensory nerve centers in the sensory nervous system. He thought that it was strictly speaking incorrect, though not uncommon, to speak of sensory centers anywhere in the central nervous system.

Dr. Potts, closing, said that he admitted that the use of the word centers was not strictly correct. He afterward changed that to spinal centers, which would be more nearly correct. Still there were in common acceptation sensory centers; they were made up of sensory neurons. In this case they would probably be in the first lumbar and lower dorsal segments of the cord. The nerves derived their supply from these particular areas, therefore they were in a sense centers.

Tumors and Cysts of the Spinal Cord and its Envelopes.—Dr. Charles K. Mills of Philadelphia read this paper, saying that he would speak first of the revival of interest in the question of spinal tumors and cysts, especially with regard to operative procedure. Special attention had been attracted to the subject recently by contributions of Horsley, Spiller, Oppenheim, Krause, Bliss, and others, who had particularly discussed the subject of chronic circumscribed meningitis in its relation to cystic formations and their surgical treatment. Dr. Mills presented the histories of three cases of intraspinal disease. The first was one of tumor of the lower cervical region; the second was a cyst of the thoracic region, similar to those which had been described under the designation of circumscribed serous meningitis; the third was a sarcoma involving the cauda equina and lumbosacral roots, and to some extent the cord. In addition to these cases several cases of intrapelvic tumor were reported with the view of emphasizing the differential diagnosis between spinal and pelvic growths. The chief points of interest in the case of subdural cervical endothelioma were the exact localizing phenomena present—early pain at the upper pole of the growth as indicated by its distribution, the moderate but distinct atrophy, and loss of power in the hands and fingers. Compression of the pyramidal tracts, as shown by paresis and exaggerated reflexes in the lower extremity, and impairment of the reflexes in the upper extremity on the side of the tumor. Anesthesia in the case was very slight, and chiefly confined to tactile loss in the postaxial portion of the hand and forearm. After the operation contraction of the pupil and ptosis or pseudoptosis were present, these apparently being caused by injury or section of communicating branches to the sympathetic. The case of thoracic "cyst" was distinctly in its appearance like those which have been described as instances of circumscribed serous meningitis. It was localized by hypalgesia, the upper limit of which was two or three inches above the umbilicus. Severe and persisting pain, both in the back and in one of the lower extremities, at first without and later with complete paralysis in both extremities, exaggerated reflexes, including the Babinski response, with bladder and rectal involvement were the most marked manifestations. After evacuation of the cyst the pain was for a time relieved, the patient recovered the use of his limbs so that at first coarse movements, and afterwards the movements of the toes, could be performed. He suffered, however, from serious cystitis and delirium, probably dependent upon toxemia. He made what might be termed a partial recovery, but relapsed. In the third case, that of sarcoma of the cauda equina and lumbosacral roots, the early manifestations were pain of an extremely severe character, which affected the back and the extremities first on one side and then on the other. In this case the anesthesia which developed indicated involvement of the posterior nerve roots, at first of the conus and later of roots higher up, as high as the second lumbar. They were distinctly root areas, not segmental or of the extravertebral neural type. The patient eventually was completely paralyzed, with marked atrophy, paralysis of the sphincters, and the whole train of phenomena showing destructive implication of the nerve roots originating from the lumbosacral spinal cord. The cord itself was also apparently involved by pressure or extensions of the lesion. The differentia-

tion between tumors and cysts because of the vacillation of symptoms in the latter was possible only in rare cases. Surgical treatment was advised in all cases like those recorded in the paper. Sometimes for radical treatment, that is, removal of the growths; sometimes for relief as by emptying the cysts; and sometimes simply for what might be termed spinal decompression. Effects comparable to those of decompression by cranial operations are sometimes brought about by operations upon the spinal column. Instead of optic neuritis, headache, nausea, and vomiting being relieved, as in cerebral decompression, the good results were seen in the relief of pains, hyperesthesia, spasticity, etc. Of course, spinal decompression must be separated from cutting posterior roots, although both might be of service in the same case.

Dr. William G. Spiller of Philadelphia said that the case of circumscribed serous spinal meningitis reported by Dr. Martin, Dr. Musser and himself was the first of its kind reported. The patient is now in perfect health, except that she occasionally had a little pain in the back, possibly from catching of some fibers. Dr. Weisenburg believed he could distinguish between a circumscribed serous meningitis and a tumor, and presented a case to prove his contention before the last meeting of the Philadelphia Neurological Society. There was no possibility of diagnosing a circumscribed serous meningitis from a tumor. As Oppenheim had pointed out, there would be variation with the fluctuation of the fluid in the dural canal. We could not have symptoms which would enable us to decide as to whether the condition was one of circumscribed spinal meningitis or tumor.

Dr. George W. Jacoby of New York presented two specimens. One had been taken from a man who had suffered with symptoms of gradually increasing pressure paralysis and paresis, and disturbance of sensation for a period of ten or twelve years. He had been able to walk to the hospital, but had marked weakness of both lower extremities. There had been sufficient sensory disturbance to enable him to make a diagnosis of probable intraspinal tumor at the sixth dorsal vertebra. At operation there had been found at this sixth dorsal segment an enchondroma growing from the body of the vertebra into the spinal canal, compressing the cord so that the cord was attenuated to simply a filament. The second case had been operated on by Willy Meyer, and a glioma removed from the cord substance. In this case the entire history of illness had been only three months. The first symptoms had been weakness of the lower extremities, which progressed so that there had been spasticity and paraplegia, and all the symptoms of complete pressure paralysis of the cord. The tumor in this case was only the size of a large cherry stone. It was easily understood how the difference in location would produce this difference in symptomatology.

Dr. George L. Walton of Boston said that with regard to the level of anesthesia as determining the position of the spinal tumor, one very practical point was to be borne in mind, namely, that the accumulation of fluid, whether in the cord itself or in the membranes, was likely to produce symptoms which might be erroneously credited to the tumor itself. It was true that in the majority of cases the point selected for operation should err in the direction of being set too high rather than too low. But if we always followed this plan we might be misled, as in a case in which he had recently had occasion to advise operation. In this case severe pain in the lower back and extending down the thighs had been rapidly replaced by paraplegia, with numbness extending nearly to the umbilicus. Finding it hard to credit the tumor itself with such rapid growth, he had been guided rather by the initial pain, and advised removing the tenth and eleventh dorsal laminæ. Operation at this point disclosed the upper limit of the tumor, above which the cord was apparently normal. If the cord has been exposed at the level indicated by the level of anesthesia, its normal appearance would have led to the erroneous conclusion that no tumor existed. He was inclined to credit accumulation of fluid with the rapid extention of sympsoms.

Dr. John Jenks Thomas of Boston agreed with Dr. Spiller in reference to diagnosing circumscribed serous meningitis from tumor. In regard to the point of differential diagnosis between growths of the spinal cord, whether from the pia or dura, he confessed that he had less confidence in our ability to differentiate them exactly. In the case that Dr. Walton referred to Dr. Thomas had been rather opposed to operation because of the intense character of the symptoms, coming on suddenly, which seemed to him to point to total destruction. Within two or three days the man had become completely paralyzed in both sensation and motion.

Dr. Hugh T. Patrick of Chicago said that the upward movement of the umbilicus when the patient, lying with his arms folded across his chest, raised his head from the pillow, known as Beevor's sign, was of service in diagnosis in spinal cord tumors. The recti muscles were not paralyzed, but the muscles below were paralyzed, and the umbilicus made an excursion of a half inch or even more.

Dr. Ernest Jones of Toronto, Can., said that he had been Dr. Beevor's assistant for a couple of years, and he would add two points. In some cases you would get it obliquely, not only drawn upwards, as one of the muscles was paralyzed below, but sometimes obliquely to the right or left, which gives a clue to the side of the tumor. Further, in cases of congenital dystrophy with paralysis the umbilicus was drawn downwards.

Dr. M. A. Bliss of St. Louis stated that he had had quite a distinct case of circumscribed serous meningitis. A laminectomy had been done, then a second laminectomy had been done, and an endothelioma had been found.

Dr. C. K. Mills, closing, said that he was not altogether satisfied with the term circumscribed serous meningitis or with the explanation which was involved in the use of this term. In the case which he reported he thought it quite possible that there had been more than was apparent. Horsley had written on chronic spinal meningitis with cysts, etc., and the probabilities were that there was a universal serous meningitis and possibly chronic meningitis, with perhaps two or three pockets, where cystic foci appeared, as in the present case. The differentiation between intrapelvic and spinal tumors could usually be made. We simply had not been careful enough.

A Case of Fracture of the Bodies of the Fourth, Fifth and Sixth Cervical Vertebræ, with Injury of the Spinal Cord.—Dr. W. H. Swan of Colorado Springs, Dr. Charles A. Powers and Dr. Howell T. Pershing of Denver presented this paper, saying that a man, aged 70, had fallen from a stumbling horse, striking on his forehead. There had been immediate motor and sensory paralysis below the neck, with evacuation of bladder and bowel, without loss of consciousness. Extreme shock, followed for some months by improvement, without restoration of ability to stand, sit alone, or turn in bed. Daily catheterization had been done, with no ill effects. Death had taken place 28½ months after injury, from uremia. Operation had been considered and rejected on account of patient's age, and the improbability that a remediable lesion would be found. Fixation of head has been deemed inadvisable. The dried preparation of the cervical spine of this patient shows no lesion of the arches or articular processes, but a moderate crushing of three bodies which could not have been remedied by operation. Localization diagnosis had been based on retention of power in deltoids and biceps, with paralysis of both triceps muscles, which indicated a lesion of the seventh cervical segment. Faradic tests indicated almost complete escape of anterior gray

horns and anterior roots. Autopsy showed the bodies of the fourth, fifth, and, to a lesser extent, the sixth cervical vertebræ to have been fractured by a crushing force, but the fragments united in normal position. The arches and articular processes showed no injury. A preliminary histological examination showed the usual ascending and descending degeneration.

Dr. Harold N. Moyer of Chicago stated that this case followed the general rule that the fifth cervical was the most frequent seat of these cervical fractures. So far as operation was concerned, this case rather favored operation. The value of operation in these cases was unquestioned. The distinguishing features for the neurologist was to understand if there was extrinsic pressure. The hematomyelia was not, of course, to be operated upon. Moyer did not wish to be understood as saying that this old man of seventy ought to have been operated on. He was speaking of the broad, general principle of operation. He believed it to be a sound rule to fix the cervical vertebræ where you had a fracture if you don't operate. At least in all the cases he had seen he had recommended fixation.

Dr. Pershing, closing, said he thought when it came to a question of operation in a case of this kind, you had to consider the individual patient, but you had to consider the advantage of accomplishing anything when you did your operation. In this case, of course, we could not have reached the seat of fracture in the bodies and done anything with them. The risk from the operation *per se* was very great, and, of course, with this particular man would have been very much greater. There were many things aside from age which made it necessary to be very cautious about operation. The question of fixation had been discussed very carefully and very earnestly, and it was decided in the negative, mainly on account of the absence of rigidity and pain; the disposition of the patient after being warned had been to keep his head still on the pillow. Also, because of his temperament, it would have been very difficult to have made him submit to fixation.

Disturbance of Sensation in a Case of Syringomyelia.—Dr. Alfred Reginald Allen of Philadelphia read this paper, stating that the concept of Brown-Sequard paralysis has needed in the past fifty odd years material revision. This was most strikingly exemplified in the question of tactile sensation. As methods of examination became more exact we found fewer reports of cases of hemisection or the equivalent lesion of the cord producing tactile anesthesia of the opposite side of the body below the lesion. At present there were many writers who questioned the occurrence of this tactile anesthesia when the lesion was strictly hemisection in extent. A case of syringomyelia had been studied as a basis of this contribution, in which there had been practically a total loss of pain and temperature over the entire body from the mandible of the jaw downward, involving all four limbs. A few scattered areas in the lower limbs impossible to define possessed a possible appreciation of heat, cold, and pain. The tactile sensation had been everywhere perfectly preserved. The histological examination of the spinal cord showed a gliomatous and syringomyelic process, isolating completely the posterior columns of the cord down to the twelfth thoracic segment. Below the twelfth thoracic segment there was, for a distance of possibly 5 cm., an albuminous infiltration of the tissue surrounding the small arteries of the anterior fissure. This process at times extended back as far as the central canal. The anterior white commissure showed degeneration by the Marchi method. The extensive dissociation of sensibility in the lower limbs was discussed. The symptom-complex and the histopathological changes were considered, and in the light of Mann's hypothesis it was held that the pathway for tactile sensation lay in the posterior columns, and that for pain and temperature in the anterolateral columns. A number of seeming inconsistencies to these conclusions were taken up and explained.

Dr. Morton Prince of Boston said that he recalled the case which he reported to this society some years ago. It was a case of stab wound of the spinal cord. It was as neat an instance of vivisection in the human being as Dr. Prince thought we could desire. It was a neat, clean-cut section of the cord, extending obliquely across from one side to the other, taking in both posterior columns, and extending towards one side to the anterolateral column to a point close to the anterior cornua. In that case there had been total loss of sensation on one side, but on the other side tactile and pain sensation were preserved. Immediately after the wound there was complete loss of tactile and pain sense on one side and it was preserved on the other. Dr. Prince said to his mind there could not be a more crucial experiment. His examination of the cord showed that there must be a path for sensation which could be located in the triangle close to the anterior cornua. There were other cases on record in which sensation had been lost when the posterior columns alone were destroyed. Therefore it seemed to him that there were two paths of conduction for sensation, one by the posterior and one by the anterolateral column. He believed that was one of the conclusions we should draw from the evidence at our disposal.

Dr. William G. Spiller of Philadelphia stated that Dr. Allen's case had been very carefully presented and very carefully studied, and he was quite sure Dr. Allen had not overlooked Dr. Prince's paper. One point was the loss of pain and temperature sensation in the lower regions. Then we might conclude regarding the thoracic and cervical regions that this case seemed to show that in the lumbar region the fibers for pain and temperature did not cross until the sixth or seventh segment. Dr. Allen's case showed clearly the fibers of pain and temperature are in the posterior columns or positively in the gray matter, though Dr. Spiller doubted that they ascend some little distance before decussation. He did not agree with Dr. Prince's findings. Dr. Spiller thought that Dr. Prince believed the pain fibers were in the posterior column. Dr. Spiller thought they were probably entirely with the temperature fibers in the anterolateral column.

Dr. Morton Prince said he did not mean to say that the pain fibers were necessarily in the posterior column, but that they were in the posterior and anterolateral columns.

Dr. Allen in closing said that this case was one of Dr. C. W. Barr's, and it was through his generosity that Dr. Allen had been able to study the specimens. Dr. Prince had said that there were two pathways for tactile sensation. That was perfectly consonant with Mann's hypothesis. All Dr. Allen accepted was the views of Sherrington, that no tactile sensation resided in the posterior column He thought very likely Mann's hypothesis explained why when the posterior column of one side was destroyed you often had preservation of tactile sensation on that side, because the anterolateral columns were brought into requisition, but that did not mean that the anterolateral were the primary paths.

A Successful Operation for Tumor of the Hypophysis.—Dr. Hugh T. Patrick of Chicago said he would like to show a case in which the hypophysis had been removed. The patient illustrated the occasional usefulness of the neurologist and the esteem in which he was held in some quarters. Last June Dr. Patrick made the diagnosis of tumor of the hypophysis in the man he presented to the association. Dr. A. E. Halsted of Chicago was called on to operate and he had the nerve to operate and removed the hypophysis successfully. The man made a beautiful recovery, and his vision, which had almost disappeared, had returned in a very large measure. He had been able

to see only very faintly, that is, the face of an individual looked like a blurred white something, and now he was able to read a newspaper.

Dr. A. E. Halsted of Chicago said that in operating on the patient he had followed the usual preparation. The anesthesia was started with ether. A high tracheotomy was done and a Trendelenburg balloon cannula inserted. Chloroform was now used for the anesthetic. The nasal cavities were packed with adrenalin gauze and the pharynx tamponed. The upper lip was raised, and an incision made in its mucous membrane about five-sixths of an inch from the mucocutaneous junction, and parallel to the alveolar process. The soft tissues were freed and the nose gradually drawn up with retractors. The septum was divided with bone forceps, and displaced upwards and laterally. The lower turbinates, the vomer, and the perpendicular plate of the ethmoid were removed. At a previous operation, at the Illinois Charitable Eye and Ear Infirmary, the middle turbinates had been removed by Dr. Norval H. Pierce. An opening was then made through the anterior wall of the sphenoidal sinus and a blue-colored pulsating mass seen. The membrane covering the tumor protruding into the opening into the sphenoid was incised. The tumor was then curetted out with a dull curette. The whole cavity, now the shape of a cylinder, one inch in diameter and five inches long, was thoroughly flushed with normal salt solution and subsequently packed with iodoform gauze. The septum was sutured back, the mucous membrane of the mouth replaced and sutured, and the tracheotomy tube removed. During the first 48 hours the patient's temperature varied from 100° to 102°, rectally, and the pulse from 100 to 120. His condition was fair, his mind clear, and he was free from pain. At the end of forty-eight hours the packing was removed and replaced immediately by the senior house surgeon. Following the repacking of the cavity the temperature rapidly rose until it reached 105°, with a pulse of 160. The patient became somnolent and could only be aroused with difficulty. This condition lasted for 24 hours. Upon removing the gauze pack and irrigating the cavity, the temperature fell rapidly until, at the beginning of the fourth day, his temperature reached normal, and from that time on no untoward symptoms developed. The patient left the hospital at the end of five weeks, free from pain, and with marked improvement in the vision. The right eye was 4/200 before operation, and at the end of the second week after operation it was 6/15; left eye was 5/200 before operation, and 6/22 after the operation. He continued to improve, resuming his occupation as driver of an express wagon on the first of December, and since that time had enjoyed good health.

Dr. James J. Putnam of Boston narrated the case of a young man, with a temporal hemianopsia and an almost complete loss of sight, in which the x-rays had shown a large sella turcica. A diagnosis of tumor of the hypophysis was made. Operation was done and a cyst containing 1½ ounces of fluid was found, and the patient made a complete recovery. The eyesight had been restored almost to normal, although considerable atrophy of the optic nerve had taken place.

Myositis Fibrosa Following Nervous Breakdown.—Dr. John K. Mitchell of Philadelphia read this paper, saying that a nervous breakdown from overwork had been followed by an attack of fever of unknown origin, with great prostration. Four months later a stiffness in the extensors of one thigh had been noticed. A like stiffness and hardness successively appeared in muscles of other parts. This increased in degree until the patient had become almost wholly crippled. A portion of muscle excised during life exhibited widespread fibrous degeneration, the muscle fibers being in some places replaced by fibrous tissue, in others pushed aside by it.

THE VALUE OF SURGICAL PROCEDURES IN THE SOLUTION OF THE PROBLEM OF RACE BETTERMENT.

By J. EWING MEARS, M.D., LL.D.,

PHILADELPHIA.

In the number of the *Boston Medical and Surgical Journal* for October 21, 1909, there appeared a contribution of mine upon the subject of "Asexualization as a Remedial Measure in the Relief of Certain Forms of Mental, Moral, and Physical Degeneration."

At the meeting of the Georgia Medical Society held in Savannah, March 22, 1910, I read a paper entitled, "The Problem of Race Betterment, Considered in its Medical, Legal, and Social Aspects." In this paper, I incorporated, as a preliminary portion, an introduction, as it were, the paper which had appeared in the *Boston Medical and Surgical Journal*. This I did as they were related in intent and purpose, and as the occasion gave me an opportunity to extend the subject and to discuss it somewhat more at length along certain lines, especially in the direction of arranging a classification of the subjects to be treated by the surgical methods proposed and the character of the operation which should be performed.

In this first paper, I designated a "class of perverts and degenerates, idiots, imbeciles, epileptics, and the vicious insane, as well as criminals of a certain type, who, as a rule, are the subjects of sexual perversions and abnormal indulgences; who are a charge to the State and communities in which they live and a constant and perilous menace to the well being and welfare of the human race, through the potentiality they possessed of propagating their kind." In these subjects I advocated the performance of a surgical operation, which it was believed would abrogate the function of the testes and control the sexual power—ligature of the spermatic cord—as a substitute for that of castration, which is regarded as a very serious mutilation of the body, and one, to the performance of which it is very difficult, if not, in the majority of cases, impossible, to obtain the consent of the individual, if an adult, or of the parents or guardians if a minor.

Experimentation on dogs, made by me, showed that the operation was feasible, so far as the occurrence of any untoward results in the condition of the testes were concerned, and the reparative process in the simple wound made was prompt and favorable. The method of operation having been shown to be correct as a surgical procedure, I was interested in studying its efficiency in securing the results which I believed of the highest importance in the treatment of the defective subjects. Invaluable as I regarded the results to be obtained in the annulment of the procreative power, there still remained that which may be justly considered a duty to the defective subject, removal through the operation, of all sexual desire.

Ligature of the spermatic cord I first advocated in the year 1894 in a paper read before the Philadelphia Academy of Surgery, as a substitute operation for castration in the treatment of hypertrophy of the prostate gland. A few years later I was led to suggest this operation in the treatment of defectives in order to produce a state of asexualization. Since then the subject has elicited quite wide attention, and the operation of "vasectomy," or resection of the vas deferens, has been performed in a large number of instances, chiefly on criminals in State penitentiaries in which it was authorized by legal enactments of the State. It has also been performed, I believe, upon defective minors in private institutions with the consent of parents or guardians.

The advantages claimed for the operation of vasectomy are "the simple character of the operation—an office operation; absence of atrophy, or cystic degeneration of the testes; no diminution of sexual power or "pleasure,"—the discharge at orgasm but slightly decreased—the production of sterilization." Reunion of the divided ends of the vas deferens, a more delicate operation than was resection, can be done, it is stated, if the subject be cured of "masturbation, insanity, or the criminal tendencies."

In performing resection one-half inch of the vas deferens is advised to be removed, the secretion of the testicle to be emptied around the pampiniform vessels, and there absorbed. "The operation has been performed upon married men who chose this means rather than criminal abortion, to prevent transmission to offspring of their own hereditary taints, such as insanity and syphilis." One operator states that in cases of those who indulge in sexual perversions, "he has refused to castrate, but has sterilized by vasectomy and cured many and many such cases." Another operator reports, "the improvement, mentally and physically, and cures are little short of marvelous in subjects who were insane, consistent (*sic*) masturbators." Another subject was cured of "sodomy and masturbation by vasectomy."

In March, 1907, the Legislature of the State of Indiana passed a bill authorizing the sterilization of "confirmed criminals, idiots, imbeciles, and rapists" in the State institutions. Over eight hundred, it is reported, have been sterilized by vasectomy. Of this number, it is stated, over two hundred were operated upon at their own request. Since this time laws of similar character have been enacted in three or four other states.

Vasotomy, simple section of the vas deferens, is not advised as an effective operation owing to the

supposed ease of reuniting the divided ends of the excretory duct of the testes, an operation not desired in case of criminals sterilized by State authorities.

I have made these liberal extracts from published articles upon the subject of the operation of vasectomy in order that the claim made for its employment in the treatment of defective subjects may be studied in connection with the consideration of the true purposes of surgical procedures, which may be instituted for their relief, as well as for the betterment of the human race through the inhibition of the procreative power.

Further study of the operation of "ligature of the spermatic cord," has led me to modify somewhat the technic in order, if possible, to increase its efficiency. I think it desirable that the ligature should be applied as high up as it can be done with due regard to its relations to the external opening of the inguinal canal—that a double aseptic ligature should be applied, and the cord divided between the ligatures—the nerve should not be included in the ligature, but it should be divided and the ends folded back so as to interfere with reunion. The secreting power of the testes being abrogated through the deprivation of the blood and nerve supply, the danger of cystic degeneration of the vas deferens would be reduced to a minimum. It is the purpose of the operation to produce, so far as is possible, the same conditions as those which follow removal of the testes, conditions which I believe to be of the greatest value in the treatment of the defective subjects.

Let us now consider the subjects included in the class of defectives who it is thought may be relieved by any surgical procedure which has for its objects the abrogation of the sexual function.

While, as I have stated above, I regard the abolition of the procreative power to be of paramount importance in stopping the flow of degeneracy, in this way relieving the State of the burden of the care of a rapidly increasing class of defectives and in promoting, in most positive manner, race betterment, I feel that an important duty rests in the selection of the surgical procedure to be employed in accomplishing this result.

It is, therefore, desirable, I think, to classify the defective subjects, and consider the surgical procedure best adopted in the treatment of each. In general, it may be stated I believe, that sexual perversions exists to greater or less degree in all subjects included in the class of perverts, degenerates, idiots, imbeciles, the vicious insane, and a certain class of criminals—rapists. In some idiots, imbeciles, and epileptics, sexual perversions may develop, even before puberty, and grow in intensity with the increasing years of the subject, despite all ordinary methods of treatment. In degenerates and perverts, a large class existing everywhere in social life, inherited or acquired sexual perversions, manifested in unrestrained gratification and debasing methods of indulgence dominate their lives and confer upon them personal qualities which make them very undesirable members of society.

In confirmed criminals, the study of their lives and of their descendants, would seem to show that the sexual instinct was not controlled in most cases, and that indulgence, in contravention of the law led, in the mildest form, to the begetting of large families of illegitimate children; in one family as reported, the number reaching fourteen.

In one class of criminals, rapists, the uncontrolled sexual appetite is the dominating factor in their criminal lives, which inspires them to commit the most atrocious assaults upon unprotected females, and for which crimes, in certain parts of our country, swift punishment is meted out at the hands of the infuriated mob by the halter, the bullet, or at the stake.

If these statements are correct and are confirmed in the experience of those whose special work it is, or it has been, to study and treat the subjects of the defective classes, then it would seem, in the employment of a surgical measure that only should be chosen which in the absolute abolition of the procreative power, at the same time exerts a controlling influence to the extent of obliteration of the function of that part of the generative system which initiates the orgasm and stimulates the act of copulation.

The testes are concerned in the generation of the fertilizing spermatozoon, accomplished through the peculiar structure of the organ provided for that purpose—the function of the organ is maintained by the blood and nerve supply. It is a fact, well established, I think, by observation, that the obliteration of the function of one organ destroys that of other organs of parts which may be associated with it—Nature, using the term in its general sense, recognizes the fact that there is no need of the associated parts as their services have, it may be said, been dispensed with, and their functions gradually cease.

In the case of the testes, castration abolishes function absolutely, and if the operation is performed *before* puberty, the sexual instinct is not generated or the sexual power of intercourse initiated. If the operation is performed *after* puberty, in the adult, the virile power may remain for a short time but gradually disappears. This, I believe, is the experience of surgeons who have performed the operation in pathological conditions and who have had the opportunity of observing the after-condition in this respect.

In the article which appeared in the *Boston Medical and Surgical Journal*, I referred to patients exhibited to the Fellows of the American Surgical Association at the time of its meeting in New York —in the New York Hospital—into the scrotal cavities of some of the number, celluloid imitations had been introduced for the mental effect, after ablation of the diseased organs.

Dr. Robert F. Weir, the eminent surgeon who had operated in these cases, writes me as follows: "Most of my cases (some ten or twelve) of removal of both testicles and substitution therefore of celluloid imitations were of a tubercular character. I can recall but two instances (having no notes at hand), where a moderate retention of the virile power (quoad desire and erection) lasted for many months after the operation. In one of these two cases, after a lapse of a year, he made sexual effort, though he said he 'wasn't as able' as he formerly was. The second one had some power of penetration and enjoyment for not longer than six months. Of my other cases, I cannot speak now without notes, but the impression is strong with me that sexual appetite and power soon passed away after my operations. In the early cases we did not know much of the possibilities of the invasion by the original infection (tuberculosis) of the vesiculæ seminales, which may influence the value of the deductions made."

The gradual cessation of sexual desire is ob-

served by horse breeders in stallions altered *after* service, although they continue to show some of the characteristics of the stallion in form and action. Partial excision of the testes is sometimes performed for the purpose of maintaining the appearance and action of the stallion in the gelding and is known among horsemen as "cutting the stallion proud."

I think, we may conclude, therefore, that in the human subject, castration or any operation which approaches it as a substitute, performed *before* puberty, prevents the initiation of the sexual desire, and that when done *after* puberty, when the sexual desire has been initiated and gratified, the virile power gradually subsides.

Dr. Charles K. Mills, the distinguished neurologist, whose views I requested on the subject, concludes in a letter to me: "that in my experience both removal of the ovaries in women, who have reached mature years, and the testicles in men, have showed, if not at first, eventually some influence in the way of sexual repression."

We are now prepared to discuss the method of operation which should be adopted in the different subjects of the classes designated and in whom the operation is authorized by legal enactment. Exacting the absolute prevention of the procreative power by surgical procedure, does not the State owe to the defective subject the removal also of the sexual desire, which is so largely associated with the condition of degeneration and which exerts a controlling influence on its development? Is it possible in the case of the idiot, imbecile, and epileptic in whom perverted sexual indulgences exist, to effect mental or physical betterment of a pronounced character, so long as the sexual desire is present as an exciting cause of perverted indulgence? Would not any operation which, as is claimed for that of vasectomy, does not involve "diminution of the sexual power or pleasure—or but slightly decreases the discharge at orgasm," fall far short of giving to the subjects of the above class the help to which they are entitled at the hands of the surgeon? Would it not be an act of gross injustice to the community, in a moral sense, to turn loose the sterilized pervert and degenerate, still endowed with sexual power, which invites them to continue their lives of degeneracy freed by sterilization from some of the consequences of their acts?

Still more, may this not be said of the rapist, whose inspiration to commit the special crime which distinguishes him, takes its origin in his possession of uncontrolled sexual desire? Unsterilized, he is unable to do much more harm, since rarely, if ever, in such cases of assault does the ability to procreate produce impregnation. The purpose of any surgical procedure in his case should include not only the betterment of future generations but the protection of the community in which he lives, by removing the inspiration to crime—suffering as it may be said he does from a form of insanity, the treatment should be directed to his present condition as well as to the prevention of the propagation of his kind.

It may be of interest to consider one statement made by an operator of vasectomy, to the effect that "reunion of the divided ends of the vas deferens, a more delicate operation than was resection, can be done if the subject is cured of masturbation, insanity, or the criminal tendencies." Speaking in a surgical sense, and without any experience to confirm results, I think it may be stated that reunion by operation of the divided vas deferens, a tube with a lumen so very diminutive, would be, so far as regards the restoration of function, impossible. Especially would this be true after a lapse of time when the proximal end of the tube would have undergone such changes as to obliterate the lumen. Furthermore, it would seem to be inconsistent with expected curative results in case of masturbators, of the insane, or the subject with criminal tendencies, to permit the function of the testes to continue with the sexual perversions which are regarded to be the exciting causes of the diseased conditions. The simple emptying of the testicular secretion upon the pampiniform vessels where, it is stated, it would be absorbed instead of its passage to the vesiculæ seminales from which it is ejaculated at the time of the orgasm, would seem to be ineffective in obtaining curative results.

In the case of mental and moral defectives, a physician of wide experience in their care and in their treatment, Dr. Martin W. Barr, Chief Physician to the Pennsylvania Training School for Feeble Minded Children, writes me as follows: "Unfortunately, I find that there are no results obtainable from an operation where the inverted or perverted sexual appetite is not restrained. In every case operated upon in my experience, there has been marked mental, moral, and physical improvement. Personally, I very much prefer *actual castration* as this leaves nothing in doubt."

This opinion is given by a physician whose extended experience justifies its expression as that of an expert, trained in the daily contact with defective subjects, young children, minors approaching adult age, and those beyond this age, who is qualified to speak with authority upon the subject.

From this evidence alone may we not conclude that an operation which restrains sexual appetite, is essential to the accomplishment of mental, moral, and physical improvement, not one which permits sexual indulgence "with pleasure, or one which does not abate sexual power, or diminish to any great extent the discharge at orgasm."

The surgical procedures advocated in promoting race betterment should in no sense be regarded as punitive in character. They should be performed as all surgical measures are, or should be, instituted for the purpose of obtaining curative results, if possible, in the defective subjects. The highest motives of philanthropy should inspire the surgeon and should guide him in his work to the position of a noble benefactor of the human race, not only in protecting future generations from the contaminating influences of a maintained flow of degeneracy, but also in bettering the unhappy defective subject, by removing the causes which contribute to his disordered condition—thus opening his mental powers to cultivation, developing his moral attributes, promoting his physical betterment, and eventually making him a useful member of society.

The Measure of the Function of the Heart.—G. Morelli describes the usual methods of measuring the functional power of the heart, and tells of the unsatisfactory nature of the results. He then puts forward a new method, which consists in a pressure of an elastic bag on the lower extremities, covered with an inelastic covering, between the layers formed by which air under pressure is injected. The pressure in the bag is measured with a monometer, being gradually increased. The arterial tension gradually augments and, according to the different reaction and capacity of the veins and heart, the author observes in the radial artery a pressure of 10, 20, 30, or more millimeters of mercury.—*La Riforma Medica.*

REPORT OF FIVE CASES OF TETANUS AND REMARKS ON THE TREATMENT OF THE DISEASE.*

By CHARLES D. FOX, M.D.,

PHILADELPHIA, PA.

Case 1.—Summary: Symptoms of benign tetanus appeared four days after the infliction of a trivial wound. Immediate onset of an uneventful convalescence after the injection of 3,000 units of antitetanic serum.

November 15 the patient, age 21, cut her right index finger with a piece of china. The wound, a superficial one, not over a half inch in length, discharged a little pus for a few days. Four days after the accident the jaw began to ache, and on the following day auditory hyperesthesia, trismus, and rigidity of the neck developed. Her temperature rose to 103° on November 22. Becoming alarmed at the increasing severity of symptoms, whose significance was suspected, the family decided upon a change of physicians. Accordingly, Dr. Charles J. V. Fries was telephoned to November 24, and the history and symptoms of the case described. For certain excellent reasons, which need not be mentioned, Dr. Fries requested me to treat the patient.

During the first visit, the afternoon of the same day, physical examination showed her pupils to be equal, normal in size, and reacting well to light and accommodation. The ocular muscles functionated well and without nystagmus. Hearing appeared to be normal. Trismus existed to the extent that she was unable to open her mouth more than one-quarter of an inch. Moderate nuchal rigidity also was apparent. The patellar reflexes were equally, and greatly, exaggerated. So pronounced was this that the slightest tap of the hammer on the patellar tendon produced a reaction so strong as to resemble that seen in old cases of spastic paraplegia. Static ataxia, spasticity, and clonus could not be elicited. Decidedly exaggerated plantar reflexes were found in association with typical bilateral Babinski sign. Her temperature was normal at this time. The patient showed no evidence of a nervous temperament. In fact, she exhibited unusual self-possession. Without having been told of the nature of the disease, she knew, as she afterwards confessed, that it was tetanus; yet her manner would not have led any one to suspect that the gravity of her illness was known to her. After the examination had been made she was told to go to bed and to remain there. The evening of the same day, November 24, 3,000 units of antitetanic serum was injected into the subcutaneous tissues of the inferior interscapular region. At the same time, the wound, a clean fissure, was completely excised under cocaine anesthesia, and the resulting exposed area thoroughly cauterized with carbolic acid. The following day her temperature was normal, and Dr. Victor Fries reported that slight improvement had occurred.

November 26 the pulse was 94 and the temperature 99.2°. There was not any decrease in the rigidity of the neck, but she was able to open her mouth about three-quarters of an inch. The patellar, plantar, and Babinski reflexes remained the same, and decided bilateral Kernig's sign was found to be present. Though the whole spinal column was rather sensitive and painful, there was not any inflammatory reaction about the two points of injection. Two days later trismus had disappeared almost entirely, and the neck was freely movable. The patellar reflexes still were much exaggerated, but the plantar reflexes had become normal and the Babinski sign had disappeared. Improvement had been noticed in the pain and tenderness of the back. The operative wound was granulating satisfactorily.

November 29 the patient commenced to leave her bed for four or five hours daily, and increasing the time so that, after a week had passed, she remained up all day. Trismus disappeared soon after December 5. Further convalescence, according to Dr. Victor Fries, was uneventful, and she commenced to go out December 15. Even then, however, the Kernig sign still was present on the left side, though the patellar reflexes had become normal.

It may seem to have been unnecessary to have kept the patient in the house for so long a time, but in view of the reflex excitability caused by the toxin of tetanus, and inasmuch as slight trismus, the Kernig sign, and exaggeration of the patellar reflexes persisted, it was thought best to be cautious, first about permitting her to get out of bed, and later to go out of the house.

Regardless of the length of the period of incubation, death resulted in 84 per cent. of 150 cases of tetanus developing from Fourth of July injuries in the United States during 1909. In these cases the average duration of the disease, after the onset of symptoms, was three and one-half days.[1] In the Rose and Carless "Manual of Surgery" the mortality of tetanus is said to be 96 per cent., when the period of incubation is under ten days; 73 per cent. when symptoms develop after the expiration of eleven to fifteen days, and 55 per cent. when the onset is delayed for from fifteen to twenty days. In his discussion of a recent paper on tetanus, C. H. Mayo[2] expressed the opinion that the mortality of tetanus is 80 per cent. when the period of incubation is less than seven or eight days, and that 80 per cent. of the cases can be saved if the period of incubation is greater than ten to twelve days. Having examined the summarized reports in the compilation, by Jacobson and Pease[3], of 203 cases of tetanus I found seven deaths out of eight cases in which the period of incubation was four days. In view of the dismal prognosis inspired by these figures it is indeed remarkable that, with a period of incubation of only four days, the disease was not more serious in the first patient reported in this paper.

The only reason I can ascribe to the comparative mildness of the disease in this patient is the fact that the wound was so superficial, and that it was constantly being torn open by the movements of the fingers. Being kept open in this manner the entrance of air was facilitated to an extent that the growth of the anaerobic tetanus bacilli was inhibited. That the condition was not tetanus scarcely seems worthy of consideration in view of the unequivocal nature of the symptoms.

The lack of severity of the manifestations and the absence of any tendency for them to become worse, after having existed for several days in their completely developed form, leads me to believe that the patient eventually would have recovered under the other recognized forms of treatment without

*Read before the Clinico-Pathological Society of Philadelphia, March 10, 1910.

resorting to the use of the serum. The prompt improvement, however, within twelve hours of the injection is presumptive evidence in favor of the use of the serum as a curative agent in developed cases of tetanus; even though in many such cases it is valueless.

Having retained in my possession the clinical records of two fatal cases of tetanus which came under my observation in St. Mary's Hospital, Passaic, N. J., these are now reported for the first time, with the kind permission of Dr. Charles A. Church.

Case II.—Summary: Period of incubation, twelve days; treatment begun three days after the onset of symptoms and twenty-two hours before death; treated with sedatives and injections of serum into various structures.

While working in a garden, September 11, 1904, Miss M. P. M., age 9, ran a splinter from a fence rail deeply into her calf muscles. Twelve days later trismus appeared. Without having received any treatment for the condition she entered St. Mary's Hospital three days after the onset of symptoms. At this time, September 26, her condition immediately was recognized as hopeless, for the reason that she had marked and constant opisthotonos, and, at intervals of a few minutes, severe general tonic convulsions, with symptoms of asphyxia. Through the kindness of Dr. Hollister, in whose service the patient belonged, the treatment of the case was placed in my hands. The wound, a deep laceration, which was filled with pus and large sloughs, was freely opened, cleansed, and deeply cauterized. The serious nature of the case and the character of the treatment can be shown in an adequate manner only by presenting, in a condensed form, the clinical record.

quantities. It is remarkable that these tremendous doses were tolerated in a girl of nine years. Not any ill effects, though, could be attributed to the administration of the drugs. In fact, their hypnotic qualities were not exhibited in the usual manner, in spite of the quantities given. It seems that there is an antagonistic action between hypnotic drugs and the toxins of tetanus and eclampsia. That such large doses were justified was demonstrated by the persistent recurrence of severe convulsions about every ten to forty minutes, by the presence almost constantly of less severe spasms, and by the fact that the patient was conscious the greater part of the time. Harvey[4] has reported a severe case of tetanus, whose period of incubation was only six days, in which recovery followed the employment of serum and hypnotic drugs in large quantities. In this case 20 grains of chloral and 40 grains of potassium bromide were administered every three hours.

In spite of the favorably long period of incubation, the outcome in Case II was fatal because of the advanced stage of the disease when the patient was admitted and because of the severity of the infection, due to neglect of the deep and filthy wound. The operation, performed by Dr. Charles A. Church, for injection of serum into the motor nerves of the infected limb, was suggested by the favorable report, that had just been published by Rogers[5], of a case treated in this manner.

Case III.—Summary: Period of incubation, six days; treatment begun with the onset of symptoms; death in two days.

A man, about 35 years of age, had the terminal phalanyx of his thumb crushed between a heavy object and the ground. The fragments of bone having been removed a palmar flap had been made

Admitted September 26, 1904, at 12:45 P.M.

Day	A.M.	P.M.	Temperature	Pulse	Respiration	Treatment	Remarks
26	. . . .	12:55	102 3/5	109	30	Morph., ¼ hypo; Atrop., 1 100 hypo.	Wound operated.
		1:15	....	....	.	Serum, 10 c.c.	Injected into or near the sciatic nerve.
	. . .	1:30	....	....	. .	By rectum—Chloral, gr. 15; Sod. brom., gr. 60	
	. . .	4:45	.....	121	34	Serum injected into Ant. crural, n. 3 c.c.; Obturator, n. ½ c.c.; Sciatic, n. 4 c.c.; Sp. subdural space, 7 c.c.	Under chloroform anaesthesia the injections were made into the exposed nerves.
	. . . .	6:00	103	112	30		
	. . . .	7:15	.....	130	27	By rectum—Chloral, gr. 5; Pot. brom., gr. 10, Tinct. cannabis, m. 5.	
	.....	8:30	.....	....	.	Morph., gr. ¼ hypo.	
	. . .	8:45	.....	....	. .	By mouth—Chloral, gr. 5; Pot. brom., gr. 10; Tinct. cannabis, m. 5; Serum, 3 c.c.	Injected into sciatic nerve under chloroform.
		10:10	103 2/5	129	30	Chloroform anesthesia; by mouth and rectum—Chloral, gr. 10; Pot. brom., gr. 20; Tinct. cannabis, m. 5.	Necessitated by a severe convulsion.
		11:00	.....	. .	. .	Serum, 10 c.c.; Chloroform.	Under primary anesthesia equal amounts of serum injected into the three operative wounds.
		11:45	.....	. .	. .	Chloroform.	Chloroform and artificial respiration necessary during the convulsions.
27	12:45	.....	.....	....	. .	Morph., gr. ¼ hypo.	
	1:15	.....	.....	....		Tinct. cannabis, m. 10.	
	2:30	.....	103	135	28	Chloroform.	
	2:35	.....	.....	....	. .	Morph., gr. ¼ hypo. By rectum—Chloral, gr. 10; Pot. brom., gr. 20, Tinct. cannabis, m. 5.	Severe convulsions every half hour. Attacks increasing both in severity and in duration. Patient becomes conscious and decidedly asphyxiated during each convulsion.
	4:20	.....	.....	....	.	Chloroform; Tinct cannabis, m. 10.	
	5:00	.....	.....	146	27	Morph., gr. ¼ hypo.	
	8:00	.....	.....	142	35	Chloroform; Morph., gr. ¼ hypo.; Atrop., gr. 1 100 hypo.	
	10:40	. . . .	103	145	28	Morph., gr. ¼ hypo; Atrop., gr. 1 100 hypo.	Convulsions almost continuous since 10 a.m. Oxygen and chloroform given for each.
	.....	12:20	.....	....	. .		Died from asphyxia caused by a convulsion

Thus in almost 24 hours the patient was given one grain of morphine sulphate hypodermically, 45 grains of chloral, 120 grains of bromides, 40 minims of tincture of cannabis indica, 60 c.c. of antitetanic serum*, and chloroform and oxygen in unknown

*The serum used in the five cases herein reported was that of the H. K. Mulford Co. According to the method of standardization used by this company in 1904, 10 c.c. of the serum was said to possess an activity of 1,000,000 immunizing units. As made at present, 10 c.c. of serum is said to contain 1,500 units. Dr. Stewart, of the H. K. Mulford Co., informs me that it is impossible accurately to state the equivalent in present serum of 10 c.c. of that furnished in 1904. He says, however, that the present serum is almost three times as strong as the older one. Unfortunately, there are five or six different methods of standardization now in use in different parts of the world. This diversity leads to much unnecessary confusion.

and the wound tightly sutured. Six days later, April 18, 1904, trismus became apparent. At once he went to Dr. Church, who amputated his thumb in the hospital at 7 P. M. Through the kindness of Dr. Church he was then placed in my care.

case, however, hope was not entirely abandoned until the last moment, for the reason that prior to 4 P. M. the rigidity, at times, became greatly ameliorated, and we were thus led to believe that the serum was neutralizing the toxin.

CLINICAL RECORD

ADMITTED AT 7:00 P.M. APRIL 18, 1904

Date	A.M.	P.M.	Temperature	Pulse	Treatment	Remarks
18	.....	7:00	98 1/5	90	Serum, 10 c.c.	Thumb amputated. Trismus the only symptom. Can open mouth only one-half inch.
	.....	12:00	.....	80	Serum, 10 c.c.	
19	2:30	.....	.....	...		Neck has become rigid.
	4:00	.....	.....	...	Serum, 10 c.c.	Subsultus tendinum has developed.
	10:00	.....	98	68	Serum, 10 c.c.	Opisthotonos now present constantly. General tonic spasms about every two hours or less.
	11:45	.....	100 2/5	76	Chloral, gr. 30; Sod. brom., gr. 60	
	.....	2:10	.....	...	Serum, 10 c.c.	Unable to swallow.
	.....	4:30	.....	...	Serum, 10 c.c. By rectum—Chloral, gr. 20; Sod. brom., gr. 60.	Back painful.
	.....	5:30	100 3/5	97	By mouth—Chloral, gr. 30; Sod. brom., gr. 10.	Is able to swallow.
	.....	7:00	.....	...	Serum, 10 c.c.; Bromide, gr. 10, by mouth	Profuse perspiration.
	.....	8:00	.....	...	Bromide, gr. 10, by mouth; Serum, 10 c.c.	Feeling better, but spasms are more frequent. Short periods of light sleep.
	.....	9:00	.....	...	Bromide, gr. 10, by mouth	Tongue lacerated by spasms which occur every ten to fifteen minutes.
	.....	10:00	.....		Bromide, gr. 10, by mouth; Serum, 10 c.c.	
	.....	11:00	101	116	Bromide, gr. 10, by mouth	
	.....	12:00	.....	...	Bromide, gr. 10, by mouth	
20	12:30	.....	.....	...	Serum, 10 c.c.; Chloral, gr. 30, by mouth	Light sleep between spasms.
	2:30	.....	.....	...	Serum, 10 c.c.	General rigidity worse.
	3:00	.....	.....	120	Bromide, gr. 10, by mouth	
	4:00	.....	100	115	Bromide, gr. 10, by mouth	Much better. Light interrupted sleep.
	4:30	.....	.....	...	Serum, 10 c.c.; Chloral, gr. 20, by mouth	
	7:00	.....	.....	...	Bromide, gr. 20, by mouth	
	8:00	.....	.....	...	Serum, 10 c.c.; Bromide, gr. 20, by mouth; Chloral, gr. 20, by mouth.	Profuse perspiration.
	10:00	.....	.....	...	Serum, 10 c.c.; Bromide, gr. 10, by mouth	Frequent mild spasms.
	11:00	.....	.....	...	Chloral, gr. 30, by mouth; Bromide, gr. 40, by mouth.	
	12:00	.....	100	107	Chloral, gr. 30, by mouth; Bromide, gr. 40, by mouth; Serum, 10 c.c.	
	.....	1:25	.....	...	Bromide, gr. 20, by mouth	
	.....	2:00	.....	...	Morphine, gr. ¼ hypo.; Atropine, gr. 1/100 hypo.; Serum, 10 c.c.	Frequent mild spasms.
	.....	3:00	.....	...	Morphine, gr. ¼ hypo.; Atropine, gr. 1/180 hypo.	Almost constant spasms of short duration.
	.....	4:00	.....	...	Morphine, gr. ¼ hypo.; Atropine, gr. 1/100 hypo.; Bromide, gr. 20, by mouth; Serum, 10 c.c.	Spasms becoming very severe.
	.....	6:00	.....	...	Bromide, gr. 20, by rectum; Serum, 10 c.c.	Artificial respiration and chloroform now necessary.
	.....	6:25	.....	...	Morphine, gr. ¼ hypo.; Atropine, gr. 1/100 hypo.; Serum, 50 c.c.	
	.....	7:20	101 4/5	142	Morphine, gr. ¼ hypo.; Atropine, gr. 1/100 hypo.	Very severe spasm. Artificial respiration, oxygen and chloroform necessary.
	.....	9:15	.....	166	Morphine, gr. ¼ hypo.; Atropine, gr. 1/100 hypo.; Serum, 20 c.c.	
	.....	11:40	.....	...	Morphine, gr. ¼ hypo.; Atropine, gr. 1/100 hypo.	Death from asphyxia during a spasm.

In this patient the convulsions became more severe and more frequent whenever an attempt was made to withhold hypnotic drugs. As the end approached chloral no longer could be depended upon, because, to have been effectual, it would have been necessary to administer such tremendous doses as to render the use of the drug too dangerous. The convulsions, too, became so severe that a more rapidly acting drug was necessary. Therefore hypodermics of morphine were employed.

Beginning at 4 P. M., April 20, the spasms became so intense and so prolonged that, without other assistance, he would have died from asphyxia. Accordingly, the method adopted was to attempt to prevent the recurrence of convulsions by keeping him as deeply under the influence of morphine as was compatible with safety. Then, when one appeared, a hypodermic of morphine was given at once, and, respiration becoming completely suspended by the spasm, artificial respiration was performed while oxygen and chloroform were administered for the purpose of relaxing the tonic spasm of the respiratory muscles. From 4 P. M. until death occurred, at 11.40 P. M., it was necessary for two nurses and myself constantly to be in his room in order to carry out this treatment as soon as the occasion arose. Considering the circumstances, it may seem like needless cruelty to have prolonged the patient's life for almost seven hours. In this

The amount of the drugs given in this case was as follows:

Total amount in 52½ hours: Sodium bromide, gr. 370; chloral, gr. 200; morphine sulphate, gr. 1 2/3; atropine sulphate, gr. 1/16; serum, c.c. 250. Total amount during the last 24 hours: Sodium bromide, gr. 220; chloral, gr. 130; morphine sulphate, gr. 1 2/3; atropine sulphate, gr. 1/16; serum, c.c. 160.

As tetanus is such an extremely fatal disease, the prophylactic treatment of wounds is of far greater importance than the treatment of the disease after it has developed. The resistance of the disease to treatment and the consequent high mortality can be understood better when we remember that tetanin, the toxin of tetanus, is said to be four hundred times more toxic than strychnine.

Prophylaxis includes freely laying open all suspicious wounds, removal of extraneous matter, thorough cauterization, and then allowing the wound to granulate. In addition to these local measures a subcutaneous injection should be made of 1,500 units of antitetanic serum. The tetanus bacillus being anaerobic lacerated wounds with deep pockets and punctured wounds, such as result from being stabbed or shot, and from stepping on rusty nails, naturally are the ones most apt to be followed by the development of tetanus. For this reason it is wise to use the serum prophylactically

in all such cases. This precautionary measure becomes a necessity when treating wounds which have been received in localities where tetanus is of frequent occurrence; as in New Jersey and in Long Island.

Just as a mild form of variola infrequently attacks successfully vaccinated individuals, so a nonmalignant form of tetanus has been known to occur, though rarely, in those who have received prophylactic injections of the serum. This is shown by the six American and Canadian cases collected by Jacobson and Pease[3], in which tetanus developed even though serum had been used prophylactically. Of these death resulted in but one. Of seven similar cases mentioned by Delbet[6] five recovered. Vaillard[7] compiled 41 French and foreign cases, including those of Jacobson and Pease, Suter[8], and Lotheisen[9], in which tetanus developed in spite of the fact that serum had been used at or near the time of receipt of the injury. Of these he discarded ten cases on account of diagnostic uncertainty or of lack of details in the reports. After studying the remainder he came to the conclusion that antitetanic serum is protective only for about ten days, and that in but five of these cases could it be considered a complete failure.

Some interesting facts concerning the prophylaxis of tetanus have been adduced by Scherck[10]. His figures show that of 56 cases of Fourth of July injuries treated other than with serum in the city dispensaries of St. Louis in 1903 16 deaths occurred from tetanus. During the three succeeding years there were not any deaths from this disease in 291 similar cases treated with the prophylactic injection of serum. The statistics of Delbet[6] relative to the increase in the number of deaths from tetanus in Paris appeared to be very damaging evidence of the value of the serum. These showed that between the years of 1886-1890, before the serum was used prophylactically in the Paris hospitals, there were 135 deaths from tetanus. During the years from 1891-1895 there were 128 deaths from the disease. Now, during the period from 1896-1900, when the serum was used as a prophylactic and as a curative agent in some of the Paris hospitals, the deaths from tetanus increased to 176. During the years from 1901-1905 there were 153 deaths from tetanus in spite of the fact that the serum was used in nearly all hospitals These cases having been investigated by Vaillard, it was found, he says, that of the 329 deaths from tetanus occurring in Paris since the introduction of antitetanic serum, only 11 of the cases had received injections of the serum.

In veterinarian practice the prophylactic use of the serum has been productive of even more satisfactory results than those which have been mentioned. Wells[11] speaks of a stable where, prior to the introduction of serum as a prophylactic agent in the treatment of all wounds about the feet, from 6 to 8 horses died from tetanus every year. During the first 5 years subsequent to the adoption of this treatment not a single case of the disease developed among 300 horses treated in this manner. According to Vaillard[7] not a single case of tetanus developed among 13,124 horses who had received prophylactic injections of the serum.

In 1906 Jacobson and Pease called attention to the possibility of infection from the intestinal tract and they collected five cases in which tetanus followed operations even though these had been performed under aseptic conditions. More recently Richardson[12] studied a group of 21 cases of post operative tetanus and found that more than 90 per cent. of these cases followed operations during which the peritoneal cavity had been opened. He concluded that these operations favored the activity of tetanus bacilli which already were present in the intestinal tract.

It has been said that the feces of 5 per cent. of ordinary men contain tetanus bacilli, and that in those who work around horses this proportion is increased to 20 per cent. It has been demonstrated, too, that the tetanus bacilli, without losing their vitality, are capable of passing through the intestinal tract of domesticated animals. The bacilli gains entrance to the human body by being ingested with uncooked food products that have been grown in soil fertilized by manure. In view of these facts, and having had two deaths from postoperative tetanus in his own practice, Matas[13] advocates thorough purging and restraint from uncooked food for three days prior to operations in regions exposed to fecal contamination. If these measures cannot be taken then 10 c.c. of antitetanic serum may be administered.

In spite of the great value of antitetanic serum as a prophylatic this agent is not as efficient when used for curative purposes after symptoms of tetanus have developed.

A fact which one always must take into consideration in the making of statistics is the inherent tendency of many physicians to report only their successful cases. For this reason any mortality percentages which are based upon compilations of the case reports in the literature must be more favorable than the reality. To my knowledge there are only three extensive compilations of reports of tetanus cases treated with serum. These are the table of Anders and Morgan[12] and the collections of reports summarized by Moschcowitz[13] and by Jacobson and Pease[3]. As the first two of these consist of material collected from the literature the mortality percentages which are deduced are entirely too favorable. Statistics based upon the collection of Jacobson and Pease must be reliable for the reason that their compilation contains abstracts of all the cases of tetanus treated in many large hospitals or by surgeans connected with these institutions and of all the cases in New York State for which the State Department of Health furnished serum.

According to Moschcowitz the use of serum has reduced the general mortality of tetanus from 90 per cent. to 40 per cent. But the more reliable statistics of Jacobson and Pease show that the mortality was 69.6 per cent. in 191 cases treated with serum. Of these cases the mortality was 84.2 per cent. in 127 cases whose period of incubation was less than 10 days, and in 64 cases whose period of incubation was greater than this, the mortality was 40.6 per cent. The statistics which Anders and Morgan and which Moschcowitz have based upon case reports gleaned from the literature and which are less reliable on this account, decrease the mortality of tetanus to 61 per cent and 51 per cent., respectively, when the period of incubation is less than 10 days. As typical of the mortality statistics of tetanus before the introduction of antitetanic serum Richter's table[13] of 205 cases of the disease may be drawn upon. This table, consisting almost entirely of cases which had resulted from

injuries received in the Franco-Prussian war, shows that the general mortality was 84.6 per cent. The mortality rose to 95.7 per cent. in 116 cases whose period of incubation was less than 10 days, while it fell to 70 per cent. in 89 cases whose period of incubation was more prolonged. Taking these statistics as standards we may say that serum has reduced 11.5 per cent. the mortality of acute tetanus, 29.4 per cent. the mortality of subacute tetanus, and 15 per cent. the general mortality.

In consideration of the extremely fatal nature of tetanus and in spite of the fact that most cases seem to be uninfluenced by serum, we are never justified in refraining from its use in the treatment of developed cases of the disease. In an editorial in the *Journal of the American Medical Association*[14] the value of the serum has been summed up as follows: "it may be stated, dogmatically, that the value of tetanus antitoxin as a prophylactic agent is very great, and its efficiency nearly absolute; as a curative agent it is by no means worthless, and undoubtedly it saves not a few lives when properly used." When using the serum for curative purposes it is advisable to administer large quantities. Harmful effects of this agent have not been known to occur and some cases seem to have been saved only by reason of the large quantity of the serum which had been used. Larned[15], for instance, speaks of an apparently hopeless case which recovered following the injection of 198,000 units.

Some years ago Roux and Borrel[16] originated the intracerebral method of injection of antitetanic serum. This procedure, since then, has been tried in a small number of cases, though not only is it dangerous but its value over others is decidedly questionable. The recovery of tetanus bacilli from a large suppurating wound, even after the patient had begun to improve, was an interesting feature of a successful case, reported by Church,[17] of intracerebral injection of serum.

Intraspinal injection of serum, evolved by Blumenthal and Jacob,[18] besides being less dangerous than intracerebral injection, is more rational and is productive of better results. The intraneural method, employed in the second case reported in this paper, is based upon principles which seem to be worthy of consideration. According to experimental research the toxin of tetanus is conveyed by the motor nerves from the injury to the spinal cord, and by injection of these nerves high in the wounded limb the upward flow of toxin is supposed to be blocked. This method, combined with intraspinal and even intramedullary injection of serum, has been strongly advocated by Rogers.[19, 5] In a recent case whose period of incubation was about 17 days which was reported by Stimson,[20] injection of serum into the sciatic nerve of the affected side was not followed by relief but, on the contrary, four days later the patient developed general tetanic convulsions. Though this patient eventually recovered the apparent inefficiency of the intraneural injection would be accounted for, according to Rogers' explanation of a similar case of his own[5] by the failure to inject all the motor nerves of the wounded limb.

Probably the most common mode of administration of serum is by means of a combination of subcutaneous and intraspinal injections.

Concerning the comparative virtues of the different methods of injection the following table, constructed from the figures of Jacobson and Pease, speaks for itself:

Subcutaneous				Combined				Intraspinal			
Acute		Subacute		Acute		Subacute		Acute		Subacute	
Cases	Mort.	Cases	Mort.	Cases	Mort.	Cases	Mort.	Cases	Mort.	Cases	Mort.
70	81.1	34	32.3	41	90.2	19	57.8	7	57.1	3	0

In this table a case was termed acute when the period of incubation was less than 10 days and subacute when it was longer than this. The heading "combined" comprises those cases in which the serum was injected into two or more different structures. According to these figures the intraspinal method is productive of the lowest mortality. Of 11 patients who received intracerebral injections of the serum only 1 recovered. The mortality, 91 per cent., when this procedure is adopted, is the highest of any of the methods.

The Baccelli treatment of tetanus consists in the subcutaneous injection, every 2 to 4 hours, of a 2 per cent. solution of carbolic acid. Commencing at a daily dose of 150 minims of this solution the quantity administered rapidly should be increased until three or four hundred minims are injected daily. In Italy, this method is said to have a mortality as low as 10 per cent., but it is thought, by many observers, that tetanus is not severe in that country. In other countries the results of this form of treatment have been unsatisfactory. Not any favorable results could be attributed to the injections in the single case, a fatal one, in which I employed the Bacelli treatment in addition to serum and hypnotic drugs.

Recently it has been discovered that subarachnoid injections of a solution of magnesium sulphate is more effectual than all other methods of treatment of tetanus. Inspired by the experimental researches of Meltzer and Auer[21, 25] and of Haubold and Meltzer,[26] Blake[27] made use of subarachnoid injections of magnesium sulphate in the attempt to produce surgical anesthesia. In this his results were not entirely satisfactory, but upon applying the same procedure to two cases of tetanus he was successful in saving one. Since then a number of cases of tetanus have been treated in this manner. The reports of these cases show that one subarachnoid injection of magnesium sulphate is capable, in a few minutes, of producing a state of complete relaxation that persists for an average of 24 hours. In this manner not only are the tetanic convulsions abolished, but the patient's strength is conserved.

The disadvantages of the treatment are: possibility of excessive secretion of bronchial mucous which, however, may be inhibited by the use of atropine; catheterization perhaps necessitated by

incontinence of urine; and, if the quantity of magnesium sulphate be too large, the danger of death resulting from the depressing effect of the drug upon the respiratory center. The strength and quantity of the solution of magnesium sulphate has varied much in the hands of those who have made use of the drug in tetanus. If possible, it would appear to be preferable to commence with a dose of 1 or 2 c.c. of a 25 per cent. solution and to increase the quantity if necessary. Four c.c. of this solution seems to be the maximum safe dose. It has been recommended to inject 1 c.c. of a 25 per cent. solution for every 20 pounds of body weight. In some of the cases that have been reported the dose seems to have been too large when determined by this posological rule.

The following table contains summaries of all the reported cases of tetanus treated with intraspinal injections of magnesium sulphate that I have been able to collect in a careful search of the literature:

Case	Reporter	Age	P. I.	Other Treatment	Dose 25% Mg.	No. of Inject.	Result	Remarks
1	Blake[27]	15	7	Serum and hyp.	4 to 4½ c.c.	7	R	
2	Blake	4	7	Serum and hyp.	1½ c.c.	1	D	Hopeless from start. Tetanus bacteriemia.
3	Logan[28]	11	9	Serum and hyp.	4 c.c. and 50 m.	2	D	Cardiac collapse. Bronchorrhea.
4	Logan	24	17	Serum	4 c.c.	2	D	Death from asphyxia during a convulsion. No good results.
5	Meltzer and Auer[25]	35	4	Serum and hyp.	1 c.c. for 18 lbs. 1 c.c. for 25 lbs.	2	D	Resp. not paralyzed.
6	Franke[29]	32	12	Hypnotics	1 c.c. to 2 c.c.	3	R	
7	Robinsion[30]	11	—	Hypnotics	3 c.c. to 4 c.c.	3	R	
8	Henry[31]	9	39		3 c.c.	3	R	Severe case.
9	Henry	19	6		6 c.c.	1	D	Severe case, collapse on fourth day.
10	Henry	9	6		2 c.c. to 2½ c.c.	2	D	Hopeless from start.
11	Henry	45	18	Serum	6 c.c.	2	D	Collapse probably due in part to the inject.
12	Miller[32]	7	7	Serum and hyp.	3 c.c. of 25% 2 c.c. of 16.6%	11	R	Bronchorrhea and resp. red. in freq.
13	Heineck[33]	17	6	Serum	5 c.c.	5	R	
14	Powers[34]	adult	10	Serum and hyp.	2 c.c.	2	R	
15	Ramond et Doury[35]	21	6	Serum and hyp.	6 c.c. to 3 c.c.	3	R	
16	Griffon et Lian[36]	18	14	Serum and hyp.	2 c.c.	2	R	
17	Tanton[37]	adult	8	Serum and hyp.	12–15 c.c. of 7%	3	D	
18	Debre[38]	8	—	Serum and hyp.	2 c.c.	1	D	Death from asphyxia during a convulsion. Inj. should have been repeated.
19	Winthrop[39]	13	9	Serum and hyp.	3 c.c. to 4 c.c.	3	R

24	Fox	41	5	Serum and hyp.	3 c c. of a sat. sol.	1	D	Injection was beneficial. Probably prolonged life many hours. Death from asphyxia during a convulsion. Very severe case.

A study of this table shows that 11 cases having died the general mortality was 45.8 per cent. Of 22 of the cases in which the period of incubation was known there were 16 in which this was 10 days or less, and 6 cases in which the period of incubation was greater than 10 days. The mortality in the acute cases was 50 per cent. and in the chronic cases 33 per cent.

These figures seem to indicate that intraspinal injection of magnesium sulphate, in combination with other forms of treatment, offers the greatest chance of cure. Naturally, statistics drawn from these few cases are open to the same objections that I have mentioned in speaking of the unreliable nature of all statistics based upon compilations of cases drawn from the literature. Even so, the magnesium sulphate treatment in individual cases seems to have been productive of more immediate, more decided, and more lasting beneficial results than those which are obtained by the other methods in vogue. When employing this treatment it may be necessary to make use of morphine, bromides, and chloral, and it is advisable to administer serum for the reason that magnesium sulphate is not a cure for tetanus. The treatment may be looked upon only as a means to prevent exhaustion of the patient by reason of the tremendous amount of energy that would be expended in tetanic convulsions and, in this manner, his natural forces of resistance, assisted by antitetanic serum, are enabled more successfully to combat the infection.

Case IV.—Summary: Period of incubation, four or six days; magnesium sulphate treatment ineffectual; recovery probably due to chloral and sodium bromide; a severe case.

Between April 23 and April 25, 1910, the patient, a boy of twelve, while playing around a stable ran a nail a short distance into his great toe. Four or six days later rigidity appeared, first in the jaw, and then rapidly increased so that his jaws became completely locked and his whole body extremely rigid. At this time, May 4, he entered the West Philadelphia General Homœopathic Hospital. Opisthotonos was so great that he was unable to lie upon his back; yet there was little tendency to tonic convulsions. Although entirely healed the wound was opened up and thoroughly cauterized with carbolic acid. At first he was given subcutaneous injections of increasing doses of a saturated solution of magnesium sulphate in addition to subcutaneous injections of antitetanic serum. As his condition rapidly was becoming extremely grave, is was decided to administer magnesium sulphate by means of the intraspinal route. So rigid were his muscles that it was impossible to palpate the crests of the ilium, and, opisthotonos being extreme, it was with difficulty that a needle could be introduced between the vertebræ. The first intraspinal injection of 25 minims afforded little if any relief, so increasing doses of sodium bromide and chloral were ordered. A second intraspinal injection was attempted the next day, but the needle probably did not enter the dural sac and no effect was noticed. After this magnesium sulphate was abandoned. It was found necessary to administer as much as 10 grains of chloral and 60 grains of sodium bromide every four hours in order to produce any effect at all. After giving 27,000 units of antitetanic serum during the first two days without any signs of improvement this treatment was discontinued. After the patient had been in the hospital five days he began slowly to improve and the hypnotics were gradually withdrawn so that at the end of four days all medical

treatment was discontinued. Subsequently the symptoms gradually improved, and he was discharged perfectly well June 6, 1910. During the height of the rigidity the patient exhibited scarcely any stupor in spite of the large amount of chloral and bromide that was being administered. But during the withdrawal of these agents increasing stupor became apparent, and even after the drugs had been discontinued for several days he was more stuporous than at any time before. The stupor gradually disappeared during the course of twelve or fourteen days.

CASE V.—Summary: Period of incubation, five days; treated with serum, hypnotics, and intraspinal injections of magnesium sulphate; death on the fifth day.

May 19, 1910, a woman, æt. 41, bruised her thigh, but there was not any break in the continuity of the skin. The same day she swallowed a sharp piece of bone which seemed to cut her throat. During the evening of May 24 slight nuchal rigidity and pain appeared and she bit her tongue several times. The following morning trismus, headache, and vomiting developed and she was unable to swallow. May 26 the trismus had become absolute, nuchal rigidity was pronounced, the knee jerks were greatly exaggerated, and Kernig's sign was present, but there had not yet appeared any rigidity or spasms of the muscles of the extremities or trunk. Commencing early in the morning of May 26 the patient received a subcutaneous injection of 3,000 units of antitetanic serum every four hours. As she had not been able to swallow any food since the morning meal of May 25 rectal alimentation was adopted. Being called in consultation with her physician, Dr. George F. Baier, Jr., it was decided not to begin treatment with hypnotics and injections of magnesium sulphate until the condition became severe enough to necessitate such measures. The period of incubation being short a severe type of the disease was expected, and, consequently, it seemed best to reserve these methods of treatment for the period when they would be most needed. May 27 in the afternoon opisthotonos appeared and the patient began to have frequent attacks of slight general twitching. From the onset of symptoms she had expectorated profusely but now each attempt to raise mucus resulted in laryngeal spasms. Moreover, respiration was somewhat superficial and cogwheel in type. So hyperesthetic had she become that the preparations for lumbar puncture brought on a severe and prolonged general tonic convulsion, with almost complete suspension of respiration. Asphyxia being imminent she was quickly chloroformed and 3 c.c. of a saturated solution of magnesium sulphate was then injected after removal of about an equal quantity of clear spinal fluid. About a half hour later the rigidity had entirely disappeared except from the muscles of the head and neck. Rectal injections of 5 grains of chloral and 60 grains of sodium bromide were then commenced; the mixture being administered every six hours, or more frequently as the occasion arose. Three hours after the injection of magnesium sulphate the patient's respiration became more labored and superficial and the secretion of mucus more profuse. These symptoms continued about ten hours and though alarming they were kept under control by three injections of atropine, gr. 1/100 each. At 4 A.M., May 28, a severe tonic convulsion developed affecting only the respiratory muscles and those of the head and neck. In the course of this attack, which lasted about two minutes, the tip of the patient's tongue was bitten off. During the morning of May 28 and the previous night the patient was comatose and her extremities continued to be completely relaxed. Even the trismus had almost entirely disappeared. Towards afternoon she became delirious and her temperature, which had been gradually increasing from May 26, had risen to 104°. Later in the afternoon the delirium disappeared and the patient was able to recognize members of her family and to talk with them. Decided spasms only of the muscles of the head and neck and of respiration commenced in the evening; one being severe enough to necessitate the use of chloroform. As the muscles of the extremities were completely relaxed it was thought inadvisable to repeat the intraspinal injection at that time. Accordingly 10 grains of chloral and 90 grains of sodium bromide were administered by rectum every four hours and as often as necessary in the intervals. Death from a prolonged spasm of the respiratory muscles occurred May 29 at 6.30 A.M. The one injection of magnesium sulphate produced what appeared to be complete paralysis of both the upper and the lower extremities. At the end of about twenty hours voluntary use of the extremities returned, but until death occurred not any of the spasms affected the muscles of the extremities. The injection did not appear to exert any effect upon the rate of the heart or upon the character of its action. The poor quality of the respiration was aggravated but there was not any decided change in the respiratory rate. In Miller's case, however, the respiratory rate dropped to 7 per minute after one injection and as low as 5 per minute after another. Urinary retention was not produced by the drug; the urine continuing to be voided involuntarily. The probable location of the point of infection in the upper alimentary canal may have had some bearing upon the early development of respiratory symptoms and dysphagia, and upon the great intensity of these manifestations as compared with the symptoms dependent upon spasmodic muscular activity in other parts of the body.

ELECTRIC SLEEP IN PATHS OF DISPLACEMENT CURRENTS: NEW FINDINGS.

BY LOUISE G. ROBINOVITCH, M.D.,

NEW YORK.

AT the annual meeting of the American Medical Association, held at St. Louis, June, 1910, we presented, in the Section of Pathology and Physiology, studies on "electric" sleep. The currents used were direct currents frequently interrupted, as well as displacement currents. In order to eliminate all doubt as regards the effects of displacement currents on animals, we studied the effects of these currents on muscle-nerve preparations of frogs. The reactions obtained both by "unipolar" and "wireless" methods showed conclusively the positive effects of these currents. Sleep obtained in dogs placed in paths of displacement currents was not a misinterpretation.

Since the above meeting we have made further studies of muscular reaction in paths of displacement currents. In our first studies the muscle was not insulated; the stand holding the muscle-nerve preparation was upon an ordinary table. It was naturally supposed that in the "unipolar" as well as the "wireless" reaction the "grounding" of the preparation was a foregone conclusion. The myograms shown here demonstrate that excellent reaction is also obtained when everything connected with the experiment is insulated. The experiment was conducted as follows:

An insulating platform made for a twenty-four plate static machine was used. The legs of the platform are one foot high and two inches in diameter. The apparatus, muscle-nerve preparation, registering drum, as well as the operator, were upon this platform. The muscle reactions registered in the accompanying myograms demonstrate that "grounding" of the preparation is not necessary; that the currents affecting the tissues in this case are currents of free waves in the air; there are no grounded waves here.

It is not necessary to report here the complicated experiments requiring special and rare apparatus unknown to the profession. With special apparatus may be shown reaction at considerable distance with wireless currents. It is more useful to present here the traces registered in the accompanying myograms, showing wireless reaction at short distances and unipolar reaction. The apparatus used is a simple primary coil without the secondary coil. Every experimenter can verify these results.

This primary coil is ten inches long; it is made of six layers of wire; the diameter of the wire is 12/10 mm.; the core is one inch in diameter. The interrupter is a ribbon vibrator. The direct current used for running the coil is 120 volts of one-half ampere. There is a condenser on the primary current.

The muscle-nerve preparation, the registering drum, the coil, as well as the operator, are upon the platform. The muscle-nerve preparation is covered with a glass globe. There are two non-polarizable electrodes in the wet chamber; these electrodes are filled with a saturated solution of zinc sulphate; wires connect these electrodes with binding posts on the disc of the wet chamber. The nerve of the preparation lies across the two non-polarizable electrodes.

The primary coil is put into function by turning on the direct current. The reactions obtained are explained below.

Myogram No. 1.

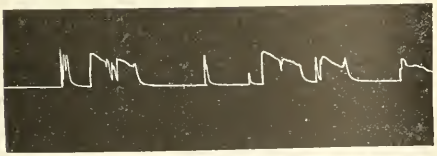
Myogram No. 1. Wireless method.—One end of a wire is screwed into one binding post of the wet chamber; the free end of the wire is held by the operator with his hand near the magnetic flux—two inches away from the core.

Myogram No. 2.

Myogram No. 2 Unipolar reaction.—Operator touches with free end of wire anode or cathode of binding post of direct current running primary coil. This reaction is also obtained when switch connecting the two binding posts is open. These latter reactions are more marked in the beginning of the experiments—before the muscle becomes exhausted. In these experiments the reactions died away with contact of the negative pole before they did with that of the positive pole.

Myogram No. 3.—Operator touching with free end of wire metallic rod near vibrator; with the other hand any metallic part of the registering drum

holding this trace or any metallic part of stand of wet chamber.



Myogram No. 3.

Reaction was also obtained as follows: An assistant standing on concrete floor touched with one hand the free end of wire attached to gas jet (the direct current is a three-wire current, the neutral wire being grounded), with the other hand he touched the free end of wire screwed into wet chamber. With this method reaction was not always obtained. Touching the free ends of the two wires gave better results, but not invariably.

There was no weight on this muscle. The frog was of splendid vitality before the muscle was dissected out from it. It had been caught in the open the day before the experiment.

Trace No. 1 leaves no doubt as regards the effect of free electric waves in the air on living tissue. Our studies on electric sleep by means of displacement currents reported at the above mentioned meeting present the following interest: The currents used by us (direct, frequently interrupted) for electric sleep as well as for surgical operation in man* cause a disagreeable sensation of tingling in the brain when applied centrally. Whereas free electric waves in the air or wireless currents do not cause any disagreeable sensation. We have demonstrated the possibility of producing physiological effects on living tissue and on animals (dogs) by means of wireless currents. In the case of the frog's muscle the work is done on a miniature scale. The displacement current was too weak to be detected with an ordinary telephone receiver. This scale will have to be enlarged for purposes of practical application in man. Further researches are now in progress for this purpose.

In view of these experiments the laboratory method of demonstrating to students muscular reaction in "wired" and "closed" electric circuits seems to be out of date, and failure to demonstrate reaction because of "bad contact" in the secondary circuit becomes amusing, when reaction can be obtained without "contact" and without secondary currents.

When an ordinary small primary coil is used, the size currently used by physicians in their induction apparatus, reaction is obtained as follows: The wet chamber is put into a wired "circuit" with a gap of from 2 to 5 centimeters; a switch in the circuit is opened to cause the gap.

But even without this gap the method is practically unipolar, because the circuit does not exist, properly speaking; it is formed as follows: one wire is fastened to any metallic part near the magnetic flux—any binding post, the operator touching with the free end of the other wire any part of the ribbon vibrator, or either of the binding posts of the switch controlling direct-current, feeding primary coil, etc. While making these contacts, additional reaction is obtained if the operator touches with the other hand the base of the stand holding the preparation, base of registering drum, or any other metallic part in the path of displacement current.

We are indebted to Dr. F. M. Law, of New York, for various suggestions in this work.

IMPORTANT EVENTS IN THE DEVELOPMENT OF GASTROENTEROLOGY.*

BY JULIUS FRIEDENWALD, M.D.,

BALTIMORE, MD.,

PROFESSOR OF GASTROENTEROLOGY, COLLEGE OF PHYSICIANS AND SURGEONS.

IN the president's address, which I had the honor to deliver last year, I attempted to draw attention to some of the important events occurring in the field of gastroenterology in America during the 19th century, and it appeared to me after this undeserved honor had been bestowed upon me again, that I could not do better than present to your consideration a few of those epoch-making events in the development of gastroenterology which have accomplished so much in placing this branch of medicine upon a firm scientific basis, and have elicited so much interest in its special study.

No one who is especially interested in diseases of the stomach should fail to read that most important article "Uber die Behandlung der Magenerweitering durch eine neue Methode mittlest die Magenpumpe" by Kussmaul in the *Deutsches Archiv fuer klinische Medicin* in 1869, in which a most ingenious method of treatment laid the foundation for an exact mode of diagnosis in gastric disturbances. In this valuable work, Kussmaul tells of the difficulties besetting the treatment of advanced forms of dilatation of the stomach due to narrowing and closure of the pylorus. "Very exceptionally was it possible to obtain any results in the treatment of this dreadful disease. As a rule it may hardly be possible ever to expect an amelioration of the symptoms, and never possible to produce a cure." Kussmaul, who was director of the Freiburg Medical Clinic, was rather reluctant in admitting to his clinic a country girl, Marie Weiner, twenty years of age, who had been troubled with gastric disturbances for 11 years, and in whom he found a typical example of dilatation of the stomach, produced by stricture at the pylorus due to ulcer. The patient was very pale and emaciated and so weak as to be unable to leave her bed; she suffered greatly from vomiting of extremely large quantities; from gastric pain, sleeplessness, and attacks of tetany and was relieved of her suffering only by means of morphine. Kussmaul says: "Often when I observed the patient in the wretched prodromal stage of vomiting the thought had occurred to me that I might relieve her suffering by the employment of the stomach-pump, as the removal of large masses of decomposed acid gastric contents should cause relief from the agonizing burning and retching at once. The introduction of the sound could be performed without difficulty, for where a gastric dilatation has existed for so long a period of time the esophagus is usually dilated. The artificial emptying of the stomach by the pump could be no more painful or distressing than the condition existing before and during vomiting; at any rate, its effect would be more rapid and complete than the emptying of the stomach by means of vomiting,

*President's address, read at the thirteenth annual meeting of the American Gastro-Enterological Association at St. Louis, June 6, 1910.

with its prolonged prodromal stage of nausea, pain, and retching. Often, even after vomiting, palpation and percussion indicated that the stomach still contained considerable masses of contents. This condition reminded me of the so-called ischuria paradoxa, in which large amounts of urine flow daily from the dilated bladder without its actually emptying itself and without reducing its size. By means of the pump it is possible to empty the stomach completely, and, if its elastic and contractile powers have not been entirely lost, perhaps even give to it the tone to contract a certain degree, as the catheter occasionally brings about recovery in ischuria paradoxa." "In our patient the gastric dilatation was occasioned by stricture at the pylorus. At the post-mortem examination of cases of extreme gastric dilatation, I have repeatedly found that the stenosis which was present would still admit the passage of a small finger from the stomach into the duodenum, although there had appeared to be complete closure of the pylorus toward the end of life. In such cases I had at times observed at the bedside through the abdominal walls active movements of the stomach. It appeared to me as though the excessive distention, the filling and overloading of the stomach itself, produced a mechanical action which increased the constriction of the pylorus to complete closure. I was desirous of removing this condition by emptying the stomach and decreasing its size. Finally, it appeared to me that the use of the stomach-pump would permit a more thorough treatment of the diseased gastric mucous membrane than was ever before accomplished. In the case of our patient this had for 2½ years been constantly irritated by extremely acid contents. The stomach-pump would not only make it possible completely to evacuate these acid acrid masses, but would permit the washing and cleansing of the diseased mucous membrane, which had been irritated by acids with alkaline fluids, as, with vichy water or with an artificial soda solution." "The introduction of the stomach-tube, the pumping out, and washing with vichy water were usually easy. We withdrew three liters of acid, dirty-gray, sarcina-containing fluid, with particles of food of all kinds undergoing softening and decomposition." This was first accomplished on July 22, 1867.

Although most enthusiastic over this new method of treatment, Kaussmaul realized its limitations. He recognized that only where slight constriction of the pylorus existed, was he able to cure cases of dilatation of the stomach by lavage. In cases of malignant stenosis of the pylorus, and marked cicatricial contraction relief only could be afforded, and not a cure. He says: "Naturally it is impossible to expect a cure of a dilated stomach by means of lavage when the pyloric orifice is narrowed to such an extent that it will hardly admit even as much as a goose quill." It is here that Kussmaul points out the possibility that surgery may at some future day bring relief to these cases, and it is possible, as Fleiner suggests, that perhaps it may have been the inspiration of this remark that led Billroth at a not very distant date to attempt to cure in curable forms of gastric disease by surgical measures. Thus a new method of treatment, this epoch-making work of the great master Kussmaul, furnished the impetus for the study of gastric diseases according to modern scientific methods and led to the use of the stomach-tube, not only as a new method of treatment but also of diagnosis.

A year later (1870) Jürgensen pointed out the disadvantage of the stomach-pump, as recommended by Kussmaul. The pump is difficult to cleanse and in fact its use is superfluous. Jürgensen here introduces the principle of syphonage into the practice of gastric lavage, which entirely eliminates the use of the pump in this form of treatment. The soft rubber tube is also here recommended, and Jürgenson fully explains the method of introduction of the stomach-tube, the position to be assumed by the patient as well as the method of practising the syphonage in freeing the stomach of its contents. This contribution must be classed as a distinct advance in the therapeutics of gastric diseases. Jürgensen utilized the rubber tube terminating in a perforated ivory bulb. The bulb was guided by means of a wire stylet. Four years later (1875) Ewald called attention to the fact that any rubber tubing having sufficient resistance could be introduced into the stomach without the use of a guide.

While Kussmaul drew attention to the therapeutic value of the stomach-tube, it remained for Leube at the Rostock Naturforscher Versammlung in 1871 to point to the value of the stomach-tube as a diagnostic measure and also to emphasize the fact that it is impossible to arrive at a proper conclusion concerning the nature of gastric conditions without the use of this instrument.

Twelve years later (1883), Leube established his test meal as a means of determining the state of motor sufficiency of the stomach, concluding that a normal stomach should be empty seven hours after the ingestion of a meal of soup, broth, steak, and bread. This test of Leube's is recognized to-day as a most valuable means of determining variations in the motor function of the stomach. Leube also at this time analyzed the gastric secretion obtained from the stomach by utilizing mechanical influences, for instance, from the irritation produced by the prolonged use of the sound; by chemical influences, the ingestion of soda-water; and by thermic stimulation in swallowing ice-water. It was not long after (1883) that Leube developed his well-known scale of the digestibility of various foods, which he earnestly advocated as a means of diet in the treatment of ulcer of the stomach. He divided the various food stuffs, according to their digestibility, into four classes. This work is most valuable, pointing as it does to the importance of diet in gastric diseases, and marked an advancement in the therapeutics of diseases of the stomach.

Riegel (1881) showed the difficulties encountered in obtaining gastric juice by stimulating the gastric secretion by means of ice-water, according to the method of Leube, as but minimal quantities are thus obtained. He therefore advised the withdrawal of the gastric contents after his well-known test dinner of soup, beefsteak, bread and water, and also established the fact that the most favorable time for removal is at the height of digestion. He demonstrated here, too, that the absence of hydrochloric acids is a usual occurrence in cancer of the stomach, though this acid is at times absent in other conditions.

In their classical work on the "Physiology and Pathology of Digestion" (1885-1886), Ewald and Boas presented their experiments regarding the appearance of free hydrochloric acid and lactic acid in the stomach contents and also drew attention to other important factors connected with the chemistry of gastric digestion. They, too, accept the height of digestion as the period best adapted for the withdrawal of the gastric secretion for the pur-

poses of examination. Ewald here fully described his test breakfast and presented its advantages as well as its importance in the diagnosis of gastric disease. The expression method of obtaining gastric juice is also described and is adopted as the simplest method for obtaining this secretion.

Van den Velden (1879), an assistant of Kussmaul, was the first to use anilin dyes as a means of detecting free hydrochloric acid, adopting the idea of Witz published several years before, who utilized these reagents in detecting free mineral acids present in vinegar found in the market. He also utilized acid rosanilin (fuchsin) for this purpose and advised the use of tropaeolin, presenting the following table indicating the change in color produced by the presence of free hydrochloric acid.

	Gastric Juice.	
	—HCl.	+HCl.
Methylanilin violet	Violet.	Light blue.
Acid rosanilin	Red.	Colorless.
Tropaeolin	Yellow.	Red.

Van den Velden also points out that there are certain cases of dilatation of the stomach which are not due to a carcinomatous stricture at the pylorus and which present free hydrochloric acid while those forms due to carcinoma usually show an absence of free hydrochloric acid.

Ewald (1880) soon combated the conclusions arrived at by Van den Velden concerning the significance of the anilin dyes in the detection of free hydrochloric acid, and some years later (1886) Cahn and Mehring also presented evidence to invalidate the significance of the anilin dyes in the detection of this secretion. These investigators were able to detect the presence of hydrochloric acid in certain instances in which Methylanilin violet no longer indicates its presence and as a consequence they declared against the use of the color reagents in the determination of hydrochloric acid. Honigmann and von Noorden (1888) also observed that the gastric juice, which did not react to color reagents still contained some acid that reacted to litmus. If a known quantity of hydrochloric acid were added to this gastric secretion a deficiency of the hydrochloric acid was afterwards always observed. This demonstrated that a certain amount of the hydrochloric acid was not free acid but combined. The necessity was therefore shown of differentiating between free and combined hydrochloric acid. A marked advance in the diagnosis of gastric diseases was made by Guenzburg's (1887) announcement of his test for the detection of free hydrochloric acid. This test reacts to free mineral acids alone, and never to organic acids. Uffelmann (1880) added another advance by the presentation of his test for lactic acids.

Reichmann (1882) was the first to draw attention to a peculiar symptom complex associated with a continuous secretion of gastric juice, in the fasting stomach. This condition was termed gastrosuccorrhea. He here reports a single case: The patient, a man of twenty-seven years, had been suffering with a digestive disturbance for six years; believing that his trouble had its origin in drinking large quantities of cold water. The symptoms manifested were pains in the stomach, heartburn, and frequent attacks of vomiting, especially after meals. The vomiting finally ceased but the pain continued, especially at night, and was most violent in the early morning.

Reichmann obtained from the stomach a liter of dirty green fluid of an acidity of 0.2 to 0.3 per cent., containing bits of bread and barley. The patient felt improved when his stomach was emptied. Lavage was then practised in the evening and yet a marked quantity (180 to 300 c.c.) of gastric fluid of an average acidity of .25 per cent. was obtained the following morning. But little attention was attached to this observation and two years later Reichmann reported a second case of the same disorder. In the following year (1885) Riegel thoroughly investigated this condition and added materially to our knowledge of the subject. His pupil Honigmann assisted in this work. Almost coincidently Sahli published his investigations in which he showed that gastric hypersecretion not only occurred continuously but also intermittently. This subject was further elucidated by Riegel, Jaworski, Gluzinski, Van den Velden, Stricker, and others, and created a considerable controversy as to whether this disorder is a disease *sui generis* or whether a gastrectasia is the primary factor in its causation.

Following the well known investigations of Beaumont, and similar experiments upon individuals having gastric fistulæ made by Richet and by Uffelmann, Penzoldt's work on the study of the digestion of food in the stomach published in the *Deutsches Archiv fuer klinische Medizin* in 1893 is most valuable. In these remarkable investigations Penzoldt describes the work undertaken by his students upon themselves under his direction. Each individual ingested certain quantities of food and removed the same at varying intervals with the tube in order to determine the length of time each food stuff remained in the stomach, assuming that the digestibility of food depends largely upon the time required for the stomach to empty itself. The experiments were undertaken by 14 students and the results collated by Penzoldt form a valuable and exhaustive investigation upon the digestibility of the various food stuffs and a most important addition to the study of modern dietetics.

The greatest credit is due J. P. Pawlow (1902) and his pupils for the many new facts discovered relating to the physiology of gastric digestion. Pawlow constructed a blind pouch from a portion of the stomach separated from the stomach itself by means of a septum of mucous membrane and communicating with the outside world by means of a fistula. He was thus able to study carefully the secretion of the gastric juice. Inasmuch as the innervation of the pouch was not interfered with, after the introduction of food into the stomach, the blind sac exhibited most clearly the secretion of gastric juice without the admixture of the food.

Among the conclusions arrived at by Pawlow, the following are most important. The amount of gastric juice secreted is proportionate to the quantity of food ingested; the secretion is acid and the more rapidly it appears the greater is the quantity of acid produced. The gastric juice appearing after a bread diet shows the most marked digestive activity; following this is the gastric juice appearing after a meat diet, and the least digestive activity is presented after a milk diet. Every variety of food stimulates a definite quantity of secretion; the average quantity of juice secreted every hour is one and a half times less after a bread diet than after a milk or meat diet, the digestion consuming a longer period of time. A latent period exists between the ingestion of the food and appearance of the secretion lasting from four and one-half to ten minutes. Nervous influences play an important rôle in the secretion of gastric juice as is demonstrated by

the fact, after feeding a dog in whom an esophagotomy has been performed (sham feeding), a certain quantity of gastric juice will appear in the gastric fistula within a few minutes.

Sham feeding has no longer any influence upon the secretion of gastric juice, provided the vagus has been severed, demonstrating the fact that the vagus is the secretory nerve of the glands of the stomach. Not only is gastric juice secreted by sham feeding, but also when the dog is tempted by the sight of food (appetite juice), the appetite being a strong stimulant to the secretory nerves of the stomach. Pawlow found that water is a weak stimulant to gastric digestion, the ash of meat as well as sodium chloride, hydrochloric acid, and soda do not stimulate the secretion; egg albumin and pure peptone have no effect on the secretion, while meat juice and beef extract are marked stimulants to the flow of the gastric juice. Starch, cane-sugar and grape-sugar have no influence, while starch paste and meat extract together markedly increase this secretion. Fats have no influence on the secretion of gastric juice, and when introduced into the stomach together with other food, diminish this secretion. Gastric digestion, therefore, is usually inaugurated by a central stimulation of the secretory fibers of the stomach glands (appetite juice); a certain time after the introduction of food, reflex stimulation begins in the stomach, while the psychical stimulation gradually disappears.

The value of surgical procedures in the treatment of certain disorders of the stomach was first discerned by the great master Kussmaul. In his work on gastric lavage he says "Naturally a cicatricial narrowing which cannot be dilated, even to the extent that a goose quill may pass through the pylorus, can never be cured by gastric lavage." "Whether in the most daring ages of a distant future an attempt may be made to produce radical results by gastrostomy and to form a gastric fistula and dilatation of the stricture by the knife or sound, no one can to-day positively assert. We fear that even the proposal of such a method of relief may expose us to silent or expressed ridicule." It was probably the inspiration of these remarks that led his friend, the great surgeon Billroth, to attempt to treat certain hitherto incurable forms of gastric disease by surgical methods. Billroth in 1877 first published a paper on a successful case of partial resection of the stomach, stating that this was but a step leading to an operation for removal of cancer of the stomach. But two years later, in reporting a similar case, he attempted to show that there were no insurmountable obstacles to the partial resection of the stomach either on anatomical, physiological, or operative grounds; "it must succeed."

Czerny and Kaiser (1878) experimented on a dog from whom they removed the entire stomach. The animal lived a long time after the operation and increased in weight. Pean (1879) was the first surgeon to perform resection of the pylorus. The patient died after five days. Rydygier (1880) performed the second operation, removing a cancer of the pylorus. The patient lived twelve hours.

Billroth and Woelfler (1881) reported four cases of partial resection of the stomach and pylorus, three of which were performed by Billroth and one by Woelfler. The first patient, Theresa Heller, age 43 years, was suffering with a large cancerous mass at the pylorus. The pyloric area was completely resected. The patient died four months after the operation. At the autopsy cancerous infiltrations of the peritoneum and of the retroperitoneal lymph glands were revealed. The second patient, Johanna Schoenstein, age 39 years, presented a carcinoma of the stomach situated in the left side between the umbilicus and arch of the ribs. The mass involved the pylorus, which was resected. The patient lived eight days after the operation and died of inanition. At the autopsy it was demonstrated that the cancer had been completely removed and no trace of peritonitis existed. The third patient, Franzika Heininger, presented a cancerous mass, rather nodulated, in the region of the pylorus. The mass was removed, the patient collapsed during the operation, and died from shock the same night. The fourth patient was operated on by Woelfler, who was given the opportunity of resecting a cancerous pylorus in a patient 52 years of age. The patient recovered from the effects of the operation, and two months afterwards was perfectly well, and was able to take all forms of nourishment without discomfort.

Woelfler (1881-1882) introduced the operation of gastroenterostomy into surgery. He first performed the operation in inoperable carcinomata of the pylorus in which complete resection of this portion of the stomach was no longer possible. Woelfler selected a portion of the jejunum about 40 cm. from the pylorus, drawing it over the transverse colon and omentum; the stomach and jejunum were finally incised and the two openings sutured together. The Heinecke-Miculicz pyloroplasty was devised by both Heinecke and Miculicz independently of each other. Heinecke's operation was first reported by Fronmueller in 1886 and Miculicz reported his operation in 1887.

I have pointed to but a few of the many contributions that have added to our knowledge of diseases of the stomach. To the great masters in medicine we owe a great debt of gratitude for placing the study of diseases of the stomach upon a firm scientific basis, and for attracting especial attention to this branch of medicine from which many of the more recent investigations in gastric diseases have emanated. Much has already been accomplished. May the great work continue, and may much in the future that is new, true, and great be accomplished under the auspices of this Association.

WHY THE EXCEPTIONAL CHILD IS ENTITLED TO RECEIVE TRAINING SUITED TO ITS NEEDS AT PUBLIC EXPENSE.*

By M. NEUSTAEDTER, M.D., Ph.D.,

NEW YORK.

ATTENDING NEUROLOGIST, NEW YORK UNIVERSITY AND BELLEVUE COLLEGE CLINIC, AND O-P. DEPARTMENT BELLEVUE HOSPITAL.

When we follow mankind in its path through centuries, beginning with the self-worshipping individual of the Greeks, on through the dark middle ages, where the value of the individual is absolutely nil, and approach the threshold of the modern era, there dawns upon us one of the most brilliant achievements of human reason in its path of progress, a most wonderful awakening of the social consciousness, the rise and development of the social sense of duty and obligation—the social conscience.

The beholder of the past meets with rather gloomy experiences; he finds villagers working as serfs, meekly submitting to oppression; men are

*Read before the conference of the Association for the Education of Exceptional Children April 20, 1910.

sold into bondage by greedy rulers; here and there chained into gangs like animals and succumbing to pitiful and heartrending suffering. One smitten by an infectious disease is cast into wilderness with neither medical care nor even a word of comfort or encouragement. But the era of enlightenment, the age of reason furnish a different picture. Hugo Grotious writes his "Jus Naturale and Jus Civile" and Herbert of Cherbury publishes his book "De Veritate." Laws are promulgated for the proper protection of the masses; the physically and mentally disabled are receiving proper care, not only are devastating epidemics combatted, but prophylactic measures for the prevention of diseases are instituted and irrespective of whether the individual is poor and incapacitated or not, he feels and knows his relation and obligation to society in general, and to the individual in particular. Here the value of the individual looms up as a positive one. And this social consciousness is manifesting itself gradually in wider circles. While Ellen Key terms the nineteenth century the century of the infant, for it is in this century that parents become more and more cognizant of their duties toward the offspring, it became the mission of the twentieth century to awaken in its social consciousness the sense of duty and obligation toward the growing generations, the most precious asset of the nation.

Fortunately, to most of our children society owes no other obligation than the shaping of the circumstances of their parents in such a manner as not to interfere with the successful progress of their progeny. In the discharge of its social obligations toward the adult, the exterminating of the slums and substituting of humane conditions for the poorest, the community has fulfilled its obligation toward the most of our children. But alongside of these—the normal and healthy children, who are in need of nothing more than parents and a home—there are thousands of abnormal, atypical, or exceptional children, who do not fit into the normal family or ordinary school environment, and to them and to itself through them society owes quite another obligation. They are in need of a particular kind of education in a particular environment and under specially trained guardianship. Thus we are facing the question: Is it the duty of the community to comply with this crying need? Shall the atypical or exceptional child receive training appropriate to its needs at public expense?

While the normal child is successfully nearing its goal in various walks of life, the atypical one is very apt to follow by-ways that may lead it on to inspiring and lofty aims or to frightful depths. A more or less nervous, eccentric, and unstable child under inexperienced supervision, or without any guidance at all, is apt to degenerate into a shiftless, turbulent, irresponsible mind, which frequently—nay, very frequently—ends in insanity or criminality; in a word, they may become leaders or misleaders. And that is exactly where the danger lies. Society suffers from these elements which are shiftless, erratic, and ineffective. They cause disturbances, they corrupt the morals, they are responsible for irrational modes of life, they harbor sinister methods in their vocations, they nourish perverse ideals and theories. The feeble-minded and otherwise abnormal and defective types of persons will, in most cases, be handed over to institutional care, or otherwise eliminated from the ranks of the struggling millions, even in childhood. But the "atypical or exceptional" cases, as we understand them to be, will not be so readily segregated and kept away from the life of society. They are apt to grow up among us as pointed out above, and become a constant menace to our institutions and to our national progress. From their ranks come the cranks, the demigogues, the mischief-makers, the trouble-brewers in homes and in public life; those whose warped mentality and eccentric intensity will distort the problems of the day. And yet if rationally trained and early disciplined they would materially add to our leadership, to the bone and sinew of our community, to some of the most valuable elements of progress.

Examples are numerous, and it is sufficient to mention the case of the boy Sidis, who discovered the fourth dimension. If this boy were put in ordinary schools and kept strictly to the required time and curriculum he certainly would not have proved so early a valuable addition to our progress, and who knows what would become of him were he not receiving proper training in a proper environment.

Is it not the manifest duty of the community, both from an ideal and a material standpoint, to pave the way of the exceptional child toward lofty aims and to bar it from debasement? Would not society act for its own best interests, would it not relieve itself of a cumbersome and dangerous burden, if the number of its insane and criminals should be materially reduced by proper prevention? Surely! But it is not only a matter of interest, righteousness as well demands this of the social body. As long as society arrogates to itself the right to punish crime, it is also its imperative duty to prevent crime, to nip it in the very bud.
